CARDIOLOGY

An Encyclopedia of the Cardiovascular System

Contributors to Volume 4

DAVID I ABRAMSON
Professor and Head of Department of Physical Medicine and Rehabilitation and Professor of Medicine, University of Illinois, College of Medicine, Chicago. Author of *Vascular Responses in the Extremities of Man in Health and Disease* and *Practical Approach to Peripheral Vascular Disorders*

MILTON W ANDERSON
Assistant Professor at the Graduate School, University of Minnesota and Consultant in Medicine at the Mayo Clinic, formerly a Fellow in Medicine at the Mayo Foundation

AARON B BENCHIMOL
Associate Professor of Cardiology, University of Rio de Janeiro, and Chief of Service of Cardiology, Hospital dos Servidores do Estado, Rio de Janeiro Past President of American College of Chest Physicians, Rio de Janeiro Author of several monographs and publications in English and Portuguese in the fields of nutritional heart disease, beriberi heart, and bundle branch block.

WILLIAM H. BERNSTEIN
[illegible] structor in Medicine at New York Medical College, Flower and Fifth Avenue Hospitals, Adjunct in Medicine at Bronx Hospital, and Clinical Assistant in Medicine at Mount Sinai Hospital, New York.

LOUIS F. BISHOP
Assistant Clinical Professor of Medicine, New York Univers[illegible]

HARRY A BLISS
Assistant Professor of Medicine, University of Illinois, College of Medicine, Chicago, Attending Physician, University of Illinois Research and Educational Hospitals, formerly a Fellow in Medicine, Presbyterian Hospital, New York. Author of publications on cardiodynamics, cor pulmonale, and rheumatic heart disease

SIDNEY BLUMENTHAL
Assistant Clinical Professor of Pediatrics, Columbia University, College of Physicians and Surgeons, New York, Associate Attending Pediatrician, Mount Sinai Hospital, New York.

KARL BRAUN
Associate Professor of Medicine, Hebrew University—Hadassah Medical School, Jerusalem, Israel, Chief of Cardiovascular Unit, Rothschild—Hadassah University Hospital, formerly Re- [illegible]

JOHN A CALLAHAN
Assistant Professor in Med[illegible] S[illegible] at [illegible] cine at the Mayo Foundation and Assistant at the Mayo Clinic.

LUIGI CARDI
Assistant at Center for Heart Disease and Rheumatic Fever, *Rome, Italy*; formerly Research Assistant, Division of Cardiology, Chicago Medical School

PHILIPPE V. CARDON, JR
Surgeon of U S Public Health Service, National Institute of Mental Health, Bethesda; Instructor in Medicine, Georgetown University, School of Medicine, Washington, D.C.; formerly Instructor in Medicine, New York University, College of Medicine, and Cornell University, Medical College, New York Coauthor of *Life Stress and Essential Hypertension.*

SIMON DACK
Associate Clinical Professor of Medicine, N[illegible] York Med[illegible] H[illegible] U[illegible] a[illegible] S[illegible] New York. Past President of American College of Cardiolo[illegible] [illegible] Cardiology and Member of Advisory Board of *Cardiology.*

K. K. DATEY

Lecturer in Medicine, Seth Medical College of Bombay, India; Cardiologist at Bombay Hospital Vice-president of Cardiological Society of India Author of publications on hypothermia, hypertension, electrocardiography, and congestive heart failure

J N. P. DAVIES

Professor of Pathology, Makerere College Medical School, Kampala, Uganda, formerly Commonwealth Fellow in Pathology, Duke University, School of Medicine, Durham, and Lecturer in Physiology, University of Bristol. He has published outstanding contributions on nutritional heart disease and endomyocardial fibrosis

DAVID T DRESDALE

Clinical Associate Professor of Medicine, State University of New York, Upstate Medical Center, Syracuse, and Associate Attending Physician and Director of the Cardiopulmonary Laboratory, Maimonides Hospital, Brooklyn. He has done outstanding work on cardiodynamics and cor pulmonale.

WILLIAM S DYE

Clinical Assistant Professor of Surgery, University of Illinois, College of Medicine, Chicago, and Attending Surgeon, Veterans Administration Hospital, Hines. Author of articles in the field of cardiovascular surgery.

ALBERT EINHEBER

Head of Department of Surgical Physiology, Walter Reed Army Institute of Research and Medical Center, Washington, D C , formerly Research Associate of Physiology, George Washington University, School of Medicine, Washington, D C. Author of articles on blood pressure

BERNARD EISENSTEIN

Instructor of Medicine, Chicago Medical School, Adjunct in Medicine, Michael Reese Hospital, Chicago.

ELWYN EVANS

Attending Physician and Electrocardiographer, Florida Sanitarium, Orlando, Florida, formerly Assistant of Cardiology Clinic, Boston Lying-In Hospital. Former Director of the Florida Heart Association. Author of articles in the fields of bacterial endocarditis, hypertension, congenital heart disease, and aneurysms of the aorta

JUAN CARLOS FASCIOLO

Professor of Pathological Physiology and Head of the Department of Physiology, University of [illegible] Aires and Professor of Physiology, University of Tucuman. President of the Biological Society of Cuyo Author of a textbook of physiology, coauthor of a book on renal hypertension Member of the Editorial Boards of *Acta Physiologica Latino-Americana* and of *Revista Sociedad Argentina de Cardiologia.*

EDWIN R. FISHER

Professor of Pathology, University of Pittsburgh, School of Medicine, Chief of Laboratories at Veterans Administration Hospital, Pittsburgh, Senior Research Fellow at U.S. Public Health Service. Author of publications in pathology.

FELIX G FLEISCHNER

Professor of Radiology, Harvard University, Medical School, Instructor of Radiology, Tufts University, School of Medicine, Chief Radiologist, Beth Israel Hospital, Boston. Author of papers on roentgen diagnosis in the cardiovascular and pulmonary fields. Assistant Editor, *American Journal of Cardiology,* an Editor of *Cardiology.*

EDWARD D. FRANK

Associate in Surgery, Harvard University, Medical School, and Beth Israel Hospital, Boston. He has done outstanding work in experimental shock.

BENJAMIN GASUL

Clinical Professor of Pediatrics (Cardiology), University of Illinois, College of Medicine; Director of Pediatric Cardiophysiology Department, Cook County Children's Hospital, Attending Pediatrician, Presbyterian and St. Luke's Hospitals, Chicago He has done outstanding work in congenital heart disease, especially angiocardiography.

GILBERT H. GLASER

Associate Professor of Neurology and Head of Section of Neurology, Yale University, School of Medicine and Yale New Haven Medical Center, Consultant in Neurology at the Veterans Administration Hospital, West Haven, Connecticut. Formerly Associate in Neurology, Columbia University, College of Physicians and Surgeons and at the Neurological Institute of Columbia-Presbyterian Medical Center, New York. Author of many articles and papers on neurological subjects and on applied neurophysiology.

JOHN W. GOFMAN

Professor of Medical Physics and Clinical Instructor of Medicine, University of California, School of Medicine, Los Angeles Author of articles on lipoproteins and arteriosclerosis, Associate Editor of *Geriatrics*

HARRY GOLDBLATT

Professor of Experimental Pathology, Western Reserve University, School of Medicine, Director of Laboratories, Mount Sinai Hospital, Cleveland, formerly Professor of Pathology, University of Southern California, School of Medicine, Los Angeles, and Director of Institute for Medical Research, Cedars of Lebanon Hospital He has done outstanding work in experimental hypertension

IRA GORE

Clinical Associate in Pathology, Harvard University, Medical School, Boston, Chief of Laboratory Service, Veterans Administration Hospital,

and Senior Associate in Pathology, Peter Bent Brigham Hospital, Boston, formerly at Michael Reese Hospital, Chicago. Author of articles dealing with pathologic processes in cardiovascular diseases

ARTHUR C. GUYTON
Professor and Chairman of Department of Physiology and Biophysics, formerly Associate Professor of Pharmacology, University of Mississippi, School of Medicine, Jackson Author of *Textbook of Medical Physiology*, and of articles on cardiac dynamics and functions of the heart.

WILLIAM F HAMILTON
Professor of Physiology, Medical College of Georgia, Augusta Past President of American Physiological Society and Honorary Fellow of American College of Cardiology Author of *Human Physiology* and of articles on mechanical aspects of vascular dynamics

KARL HARPUDER
Assistant Clinical Professor of Medicine, Columbia University, College of Physicians and Surgeons, associated with Montefiore Hospital, New York Past President of New York Society of Physical Medicine and Rehabilitation Author of numerous papers on vascular physiology and clinical and rehabilitation problems of peripheral vascular disease.

ROBERT M P HEGGLIN
Professor of Medicine, University of Zurich, Switzerland, and Attending Physician at Hospital of St. Gallen. Author of *Differential Diagnosis in Internal Medicine*, author of numerous works including several on heart failure. Editor of *Cardiologia*

HERMAN K HELLERSTEIN
Assistant Professor of Medicine, Western Reserve University Sch...

... Author of numerous publications in fields of electrocardiography, alternans, myocardial infarction, shock, and rehabilitation

WILLIAM M HITZIG
Ass...
his
pro...
Hos... New York Known for studies on circulation time, venous pressure, and cardiodynamics

JAMES HUNTER
Assistant Professor of Surgery, University of Illinois, College of Medicine and Member of Surgical Department at the Presbyterian-St. Luke's Hospital, Chicago

HUSHANG JAVID
Assistant Pro...
nois, Co...
in Vasc...
Hospital. ... ...cago, Illinois.

EUGENIO JONA
Assistant in Institute of Medical Pathology, University of Torino, Italy, formerly Research Assistant, Division of Cardiology, Chicago Medical School. A Fulbright Scholar.

ORMAND C JULIAN
Associate Professor of Surgery, University of Illinois, College of Medicine; Attending Surgeon, Presbyterian-St. Luke's Hospital, Chicago Known for his work in cardiac surgery with hypothermia and cardiac bypass.

GEOFFREY KENT
Pathologist, Alexian Brothers Hospital, Chicago, formerly Associate Director, Department of Pathology, Cook County Hospital, Chicago.

RAY WILLIAM KISSANE
Professor of Medicine (Cardiology), Ohio State University, College of Medicine, Attending Physician, University Hospital, Columbus. Past President of Ohio Heart Association, member of Board of Directors, American Heart Association. Author of papers on myocardial conditions and traumatic heart disease

SIMON KOLETSKY
Professor of Pathology, Western Reserve University, School of Medicine, and Pathologist, University Hospitals, Cleveland. Known for his work on calcific disease of the aortic valve.

JEAN LEQUIME
Professor of Cardiology, University of Brussels, Belgium, Chief of Department of Cardiology, St. Peter's Hospital. Author of *Cardiac Output* ...

...

STANLEY LEVENSON
Chief of Department of Surgical Metabolism, Walter Reed Army Institute of Research, member of National Research Council, Washington, D C Author of articles dealing with problems of wounds, trauma, and shock.

SUNG J LIAO
Director of Physical Medicine, Waterbury Hospital, formerly Associate Research Professor of Bacteriology, University of Utah Salt Lake City ...

WILLIAM LIKOFF
Associate Professor of Medicine, Hahnemann Medical College, Cardiologist, Bailey Thoracic Clinic, and Consultant Cardiologist, Einstein Medical Center, Philadelphia, formerly Cardiac Fellow, Peter Bent Brigham Hospital ...

T ...
Cardiovascular Director, Creighton University, School of Medicine, Omaha, formerly Associate

K. K. DATEY
Lecturer in Medicine, Seth Medical College of Bombay, India; Cardiologist at Bombay Hospital. Vice-president of Cardiological Society of India. Author of publications on hypothermia, hypertension, electrocardiography, and congestive heart failure.

J. N. P. DAVIES
Professor of Pathology, Makerere College Medical School, Kampala, Uganda, formerly Commonwealth Fellow in Pathology, Duke University, School of Medicine, Durham, and Lecturer in Physiology, University of Bristol. He has published outstanding contributions on nutritional heart disease and endomyocardial fibrosis.

DAVID T. DRESDALE
Clinical Associate Professor of Medicine, State University of New York, Upstate Medical Center, Syracuse, and Associate Attending Physician and Director of the Cardiopulmonary Laboratory, Maimonides Hospital, Brooklyn. He has done outstanding work on cardiodynamics and cor pulmonale.

WILLIAM S. DYE
Clinical Assistant Professor of Surgery, University of Illinois, College of Medicine, Chicago, and Attending Surgeon, Veterans Administration Hospital, Hines. Author of articles in the field of cardiovascular surgery.

ALBERT EINHEBER
Head of Department of Surgical Physiology, Walter Reed Army Institute of Research and Medical Center, Washington, D.C., formerly Research Associate of Physiology, George Washington University, School of Medicine, Washington, D.C. Author of articles on blood pressure.

BERNARD EISENSTEIN
Instructor of Medicine, Chicago Medical School, Adjunct in Medicine, Michael Reese Hospital, Chicago.

ELWYN EVANS
Attending Physician and Electrocardiographer, Florida Sanitarium, Orlando, Florida, formerly Assistant of Cardiology Clinic, Boston Lying-In Hospital. Former Director of the Florida Heart Association. Author of articles in the fields of bacterial endocarditis, hypertension, congenital heart disease, and aneurysms of the aorta.

JUAN CARLOS FASCIOLO
Professor of Pathological Physiology and Head of the Department of Physiology, University of Mendoza, Argentina. Formerly Head of Research Division of the Cardiological Institute Grego Foundation and of the University of Buenos Aíres and Professor of Physiology, University of Tucuman. President of the Biological Society of Cuyo. Author of a textbook of physiology,

EDWIN R. FISHER
Professor of Pathology, University of Pittsburgh, School of Medicine; Chief of Laboratories at Veterans Administration Hospital, Pittsburgh, Senior Research Fellow at U.S. Public Health Service. Author of publications in pathology.

FELIX G. FLEISCHNER
Professor of Radiology, Harvard University, Medical School; Instructor of Radiology, Tufts University, School of Medicine, Chief Radiologist, Beth Israel Hospital, Boston. Author of papers on roentgen diagnosis in the cardiovascular and pulmonary fields. Assistant Editor, *American Journal of Cardiology*, an Editor of *Cardiology*.

EDWARD D. FRANK
Associate in Surgery, Harvard University, Medical School, and Beth Israel Hospital, Boston. He has done outstanding work in experimental shock.

BENJAMIN GASUL
Clinical Professor of Pediatrics (Cardiology), University of Illinois, College of Medicine, Director of Pediatric Cardiophysiology Department, Cook County Children's Hospital; Attending Pediatrician, Presbyterian and St. Luke's Hospitals, Chicago. He has done outstanding work in congenital heart disease, especially angiocardiography.

GILBERT H. GLASER
Associate Professor of Neurology and Head of Section of Neurology, Yale University, School of Medicine and Yale New Haven Medical Center, Consultant in Neurology at the Veterans Administration Hospital, West Haven, Connecticut. Formerly Associate in Neurology, Columbia University, College of Physicians and Surgeons and at the Neurological Institute of Columbia-Presbyterian Medical Center, New York. Author of many articles and papers on neurological subjects and on applied neurophysiology.

JOHN W. GOFMAN
Professor of Medical Physics and Clinical Instructor of Medicine, University of California, School of Medicine, Los Angeles. Author of articles on lipoproteins and arteriosclerosis, Associate Editor of *Geriatrics*.

HARRY GOLDBLATT
Professor of Experimental Pathology, Western Reserve University, School of Medicine, Director of Laboratories, Mount Sinai Hospital, Cleveland, formerly Professor of Pathology, University of Southern California, School of Medicine, Los Angeles, and Director of Institute for Medical Research, Cedars of Lebanon Hospital. He has done outstanding work in experimental hypertension.

IRA GORE
Clinical Associate in Pathology, Harvard University, Medical School, Boston, Chief of Laboratory Service, Veterans Administration Hospital,

Author of several publications dealing with arrhythmias and congenital heart disease.

CONRAD L. PIRANI
Professor of Pathology, University of Illinois, [illegible] pital and Chief Pathologist of Army Medical Nutrition Laboratory, Chicago. Author of articles on cardiovascular and renal diseases

OLIVIER POLIS
Assistant in Cardiology, St Pierre Hospital, Brussels, Belgium

HANS POPPER
Professor of Pathology, Columbia University, College of Physicians and Surgeons and Chief Pathologist, Mount Sinai Hospital, New York; *formerly Director of Department of Pathology*, Cook County Hospital, Scientific Director of Hektoen Institute for Medical Research, and Professor of Pathology, Northwestern University, Medical School, Chicago Author of textbook, *Liver Structure and Function*

ROBERT W. QUINN
[illegible] President of Middle Tennessee Heart Association Author of articles on rheumatic fever and streptococcal infections

WILHELM RAAB
Professor of Experimental Medicine, University of Vermont, College of Medicine, Burlington and Attending Physician and Head of Cardiovascular Research at De Goesbriand Memorial Hospital, formerly Privat Dozent for Pathological Physiology at the German University of Prague and for Internal Medicine, University of Vienna, Rockefeller Research Fellow at Harvard University, Medical School, Boston Past President of Vermont Heart Association Author of three books on hormones, endocrines, and cardiovascular disorders, an Editor of *Cardiology*

NATHANIEL E REICH
Assistant Professor of Clinical Medicine, State University of New York, Upstate Medical Center, Syracuse, and Attending Cardiologist at Jewish Chronic Disease and at Unity Hospitals Author of books, *Diseases of the Aorta* and *The Uncommon Heart Diseases*

BRAM ROSE
Associate Professor of Medicine, McGill University, Associate Physician and Allergist in Chief, Royal Victoria Hospital, and Consultant in Allergy at Queen Mary Veterans Administration Hospital, Montreal Member of Editorial Boards of *Journal of Allergy* and of *International Archives of Allergy and Immunology*

STEWART M ROSE
U S Army Medical Corps, formerly on staff at University Hospital, Ohio State University, Columbus.

SIEGFRIED SALOMON
Chief of Cardiac Clinic and Associate Attending Physician at St. Vincent's Hospital, Staten Island, New York.

PHILIP SAMET
Associate Professor of Medicine and Physiology, University of Miami, Coral Gables, and Director of the Cardio-Pulmonary Laboratory and At- [illegible] ous publications on electrokymography and cardiac catheterization.

G W. H. SCHEPERS
Pathologist at E. I. du Pont de Nemours & Company, Wilmington, *formerly* Chairman of Department of Anatomy, University of Pretoria, South Africa; Director of Trudeau Foundation, Saranac Lake, New York, and Fellow of the Commonwealth Fund

PAUL SCHLESINGER
Assistant in Cardiology, Fifth Medical Clinic, University of Brazil, Rio de Janeiro Author of publications on beriberi and nutritional heart disease

HENRY A SCHROEDER
Associate Professor of Medicine and Chief of Hypertension Division, Washington University, School of Medicine, St Louis, formerly affiliated with Hospital of the Rockefeller Institute. Author of three monographs and several articles on the mechanism and symptomatology of hypertension

JACOB J SILVERMAN
Attending Physician and Chief of Cardiac Clinic, Staten Island Hospital, New York. Author of numerous publications on cardiovascular problems.

ISADORE SNAPPER
Director of Medicine and Medical Education, Beth-El Hospital, Brooklyn, formerly held a similar position at Mount Sinai Hospital, New York, and Cook County Hospital, Chicago. Former Professor of Medicine and Pathology, University of Amsterdam, and Professor of Medicine, Peiping Union Medical School. Author of monograph on multiple myeloma and of numerous articles in the fields of endocrine and metabolic diseases

DAVID M. SPAIN
[illegible] Director of Laborat[illegible] [illegible] dealing with cardiopulmonary diseases

of Internal Medicine and Chief of Cardiac Catheterization Laboratory, University of Kansas Medical Center and Instructor and Associate in Medicine, University of Kansas Medical Center. Author of works in the field of cardiodynamics.

J LINZBACH
Professor of Pathology, University of Marburg, Germany. Author of articles dealing with arteriosclerosis.

EUGENE LIPPSCHUTZ
Associate Professor of Medicine and Director of Cardiology, University of Buffalo, School of Medicine; Director of Cardiovascular Section of Buffalo General Hospital, Buffalo Past President of Western New York Heart Association and of the New York Heart Assembly.

CHARLES LONG, II
Assistant Professor of Physical Medicine and Rehabilitation, Western Reserve University, School of Medicine; and Associate Chief of Physical Medicine and Rehabilitation, Highland View Hospital, Cleveland

ALDO A LUISADA
Professor of Medicine and Director of Division of Cardiovascular Research, Chicago Medical School, Attending Cardiologist, Mount Sinai Hospital, Chicago Formerly Professor of Medicine, University of Ferrara, Italy, and Instructor of Physiology and Pharmacology and Lecturer in Medicine, Tufts University School of Medicine, Boston. Author of *Cardiologia, Heart, Heart Beat;* coauthor of *Intracardiac Phenomena*, and *Treatment of Cardiovascular Emergencies*, author of important contributions in the fields of electrobronchography, phonocardiography, electrokymography, pulse tracings, and acute pulmonary edema. Editor in Chief of *Cardiology*

JOSHUA LYNFIELD
Clinical Assistant, Northwestern University, Medical School, Associate in Cardiophysiology and Associate Attending Physician, Cook County Hospital, Chicago, formerly Assistant Lecturer in Surgery, Post Graduate Medical School, London His publications deal with atrial septal defects

R. B. LYNN
Associate Professor of Surgery and Markle Scholar in Medical Sciences, University of Saskatchewan, Visiting Consultant to City Hospital and St. Paul's Hospital, Saskatoon, Canada, formerly Assistant Lecturer in Surgery, Postgraduate Medical School of London, England

IRVING MACK
Clinical Professor of Medicine, Chicago Medical School, and Research Associate in Cardiology and Associate Attending Physician, Michael Reese Hospital, Chicago He has numerous publications in the fields of electrocardiography and cor pulmonale.

M. MALINOW
Chief of Research, Institute of Physiology, University of Buenos search at Cardiology Pavilion of the Hospital Mejia, Buenos Aires; formerly Research Fellow in Cardiology, Michael Reese Hospital, Chicago anc [illegible] Yo[illegible] trocardiography and on experimental atherosclerosis. An Editor of *Revista Argentina de Cardiologia*

FRANKLIN C. MASSEY
Assistant Professor of Medicine and Chief of Cardiac Clinics, Hahnemann Medical College and Hospital, Philadelphia; Consultant in Internal Medicine and Cardiology to the Insurance Company of North America Companies and to the Department of Medicine, Bryn Mawr Hospital, Bryn Mawr. Author of publications on cardiopulmonary diseases, Editor of *Clinical Cardiology*

STEPHEN C MATHEWSON
Assistant in Medicine, St. Elizabeth Hospital, Boston.

EDWARD MEILMAN
Clinical Associate Professor of Medicine, State University of New York, Upstate Medical Center, Syracuse, Chief of Department of Medicine at Long Island Jewish Hospital, formerly Associate in Medicine, Howard University, Medical School and Research Associate at Beth Israel Hospital, Boston His publications are in the field of hypertension

ARTHUR A MILLER
Assistant Professor of Psychiatry, University of Illinois, College of Medicine and Associate Attending Psychiatrist at Institute for Psychosomatic and Psychiatric Research, Michael Reese Hospital, Chicago

BLAS MOIA
Extraordinary Professor of Medicine, University of Buenos Aires, Chief of Department of Cardiology, Mejia Hospital, Buenos Aires Author of three books and over 150 publications in various fields of cardiology Director of *Revista Argentina de Cardiologia* An Editor of *Cardiology.*

TAKASHI NAKAMURA
Professor of Medicine and Chairman of First Department of Internal Medicine, Tohoku University of Medicine, Sendai, Japan Well known for his studies of the bronchial circulation in experimental and clinical conditions of chronic cor pulmonale

JEROME NOBLE
Instructor in Medicine, New York Medical College, Flower and Fifth Avenue Hospitals and Associate Visiting Physician at Metropolitan Hospital, New York, formerly Lieutenant Commander in the Medical Corps, U S Navy

IVAN PINTO
Honorary Lecturer in Medicine, G S Medical College, University of Bombay [illegible]

Foreword

This work is at once a landmark in clinical cardiology and an indication of the Golden Age of Medicine in which we now live. Because wondrous things have become commonplace, we can appreciate this age only in retrospect. From rude beginnings it is possible to trace, over the centuries of recorded history, the gradual refinement in skills, the slow accumulation of factual knowledge, and the emergence of a scientific discipline so essential to success in the walks of science Progress, painfully slow and often faltering till late in the nineteenth century, then began to accelerate at an ever-increasing rate. Within the memory of some now living, individual triumphs in scattered departments of science combined in one mighty triumphant flourish to usher in the modern era. Epidemics, once the scourge of man, were abolished, certain diseases, once relentless in their course, were controlled, old age, once a rarity, became the rule. It is unlikely that within a comparable period of time man will ever again repeat the stupendous feat of doubling his span of life.

Cardiologists, while sharing in these triumphs, saw heart disease assume the lead as a cause of death in many countries. Thus, although gratified by the increased longevity of man, we are nevertheless challenged by the disclosure that the cardiovascular system is now the weakest strand in the thread of life. Indeed, its relative importance in the lives of men appears destined to increase, for there is nothing in sight pointing to a major break-through in the prevention of heart disease in old age.

In sponsoring this encyclopedia, the American College of Cardiology, dedicated to the continuing education of its membership, is simply fulfilling one of its obligations That this particular obligation weighed more heavily on the minds of some of its officers than on others raised the question of the relative merits of different methods of postgraduate education. We cannot here record the deliberations which finally led to approval of this undertaking, but they reflected the need for putting on record the widening horizons of our knowledge of cardiovascular disease

That the presentation of information concerning the heart and circulation requires four volumes involving upwards of 250 authors has important implications. It is evidence that narrowing of interest and progress go hand in hand, and that subdivision within the field of cardiology is well established But this subdivision, so essential for progress, must be reconstituted for those whose clinical responsibilities cover a broad area In effect this encyclopedia represents such a reconstitution. It contains authoritative information abstracted from an immense mass of medical literature which could not be reviewed effectively by an individual The organization of this material is based on a logical framework

MARIO STEFANINI
Associate Professor of Medicine and Lecturer in Pharmacology, Tufts University, School of Medicine, and Director of Hematology Laboratory, St. Elizabeth Hospital, Boston. Author of books, *Pernicious Anemia* and *Hemorrhagic Disorders*, and of articles in the field of hematology.

PETER TALSO
Associate Professor of Medicine, Loyola University, Stritch School of Medicine, Senior Attending Physician at Mercy Hospital, Chicago; formerly at the University of Chicago, School of Medicine.

MATTHEW TAUBENHAUS
Attending Physician, Michael Reese Hospital, Chicago. Author of articles on the hormonal influence on connective tissue

CHARLES BRUCE TAYLOR
Associate Professor of Pathology, University of Illinois, College of Medicine, and Associate Attending Pathologist and Director of Surgical Research, St. Luke's Hospital, Chicago, formerly at the University of North Carolina. His publications cover a wide field including vascular diseases, arteriosclerosis, and the metabolism of cholesterol

C. GEORGE TEDESCHI
Associate Professor of Pathology, Boston University, School of Medicine, and Pathologist at Framingham Union Hospital, formerly Head of Department of Pathology, Hahnemann Medical College and Hospital, Philadelphia, and Professor of Pathology, University of Ferrara, Italy He has published 150 articles including outstanding work on rheumatic carditis.

JEROME S. TOBIS
Professor and Director of Department of Physical Medicine and Rehabilitation, New York Medical College, Flower and Fifth Avenue Hospitals, New York. Author of articles on rehabilitation of cardiovascular patients.

DOROTHEA TURNER
Assistant Professor of Medicine and Chief Medical Nutritionist, University of Chicago, School of Medicine, Chicago. Author of book, *Handbook of Diet Therapy;* Editor of *Journal of the American Dietetic Association.*

RUSTOM JAL VAKIL
Consulting Physician and Cardiologist, at the Medical College and the Grant Medical College, Bombay, formerly Lecturer in Medicine at these colleges. President of the Cardiological Society of India. Author of over 200 papers and especially known for his studies on *Rauwolfia.* An Editor of *Cardiology.* Recipient of the Albert Lasker Award.

WILLIAM H WEHRMACHER
Instructor in Internal Medicine, Northwestern University, Medical School, and Attending Physician in Cardiology, Passavant Memorial Hospital, Chicago; formerly an Instructor at State University of Iowa, College of Medicine, Iowa City He has published several articles on cardiology and on hypertension.

A W WILLIAMS
Professor of Medicine, University College of East Africa, Kampala, Uganda, and Lecturer of Physiology and Medicine, Uganda Medical School. He has written several papers on nutritional heart disease.

STEWART WOLF
Professor and Head of Department of Medicine, University of Oklahoma, School of Medicine, Oklahoma City, formerly Associate Professor of Medicine, Cornell University, Medical College, New York Author of monographs and articles dealing with headache, life stress and essential hypertension, and psychosomatic disorders.

LEO ZIMMERMAN
Professor and Chairman of the Department of Surgery, Chicago Medical School, and Attending Surgeon at Michael Reese Hospital and Cook County Hospital, Chicago. Author of numerous articles in the field of surgery.

Preface

This work was started as a result of a bold and far-sighted initiative of Dr. Ashton Graybiel, then president of the American College of Cardiology.

The task of editing an encyclopedia of cardiology represents a challenge which is both appealing and frightening.

Among the multitude of books of cardiology which have been published in the last 20 years, the majority belongs to the type of the medium-sized, monographic textbook written by a single author. A few have been written in collaboration by several authors. These, however, do not attempt to be complete and are, moreover, too unsystematic to be helpful. Being of the "fixed-volume" type, they are soon outdated and, therefore, forgotten

In ancient Greece, *encyclopaedia* meant "instruction in the whole circle, or complete system of learning" In a more restricted sense, encyclopedia means "a system or classification of various branches of knowledge, a subject on which many books have been published." While many encyclopedias of the past have been of the "alphabetical type" (each word to be explained is listed in alphabetical order), others have tried to reconcile system with completeness Thus, even in the early editions of the *Encyclopaedia Britannica*, the various sciences and arts (such as anatomy or surgery) were "digested into distinct treatises or systems" On the other hand, technical terms were explained in alphabetical order. Older encyclopedias, like Plinius's *Natural History* of the year 77 A.D. (37 books with 2,493 chapters) or *Yung-Lo Ta Tien*, the Chinese encyclopedia of 1403 A.D. (11,095 volumes prepared in four years by over 2,000 scholars), were developed according to system. The latter even included well-known books reproduced without change

In the opinion of the editor, a modern encyclopedia of cardiology ought to have the following characteristics. (1) It should encompass all available knowledge on the heart and vessels, including history, embryology, anatomy, physiology, physical and technical methods of examination, bacteriology and pathology, clinical sciences, surgery, pharmacology and therapy, rehabilitation, and the various "allied fields." (2) It should present them in a systematic order, thus permitting easy consultation (3) It should be of the loose-leaf type, in order to keep abreast of medical progress It is then possible that some of the readers may prefer to call this a *treatise*

The principle of extending the work to all kinds of knowledge in the cardiovascular field should not be carried too far in the marginal fringes of medical or technical sciences. This process would divert and distract the attention of the reader and would render consultation too difficult. Therefore, a process of selection and limitation is an important part in the preparation of an encyclopedia of

which constitutes a resynthesis of the important elements in the field of cardiology.

In using this encyclopedia, the physician must let go of his inclination to be taught, and cultivate the art of selecting new items of information and fitting them into a frame of reference dictated by his needs. This method does require a capacity for mental independence and is effective only in so far as this is exhibited by those for whom the encyclopedia is intended. Admittedly a work of this sort represents a form of communication in which there is much redundancy. At what point will the evil of redundancy equal or exceed the good contained in the message? Herein lies a very real problem with which we should be concerned in the future.

It is noteworthy that in the compilation of this work we are more dependent upon an editor than upon an author. The choice of Dr. Luisada to edit the work has been fortunate. He has exhibited not only a natural talent for this task but also the quality of persevering in the face of difficulties. To him alone belongs the credit for bringing the encyclopedia to fruition The present handbook must be regarded as a monument to his genius.

ASHTON GRAYBIEL

2. Selection of persons with diversified knowledge (physiology, pathology, pediatrics, surgery, etc.), so that all fields may be covered by competent editors.

3. Choice of as many young scientists as possible, in order to have a high potential of enthusiasm, criticism, and working capacity.

The final product will reveal whether these directives are sound and have been followed as closely as possible.

The publication of this encyclopedia was made possible by the continued support of the American College of Cardiology through the action of its board of trustees, by generous contributions of five pharmaceutical houses, and by the warm collaboration of the McGraw-Hill Book Company, Inc., Blakiston Division.

ALDO A. LUISADA
Editor in Chief

cardiology. It is likely that a four-volume, 5,000-page encyclopedia would represent the optimal size. However, practical considerations indicate a more limited approach for the first version. Therefore, a four-volume, 3,600-page size is considered for the first edition, even though gradual revision and extension over the following ten years will probably increase the size to that previously mentioned.

Several titles have been considered for this encyclopedia. The one preferred by the editor, *Encyclopedia of Cardiology*, has been discarded for fear of discouraging prospective readers. The more modest title which has been selected—*Cardiology*—emphasizes the main scope [knowledge about the heart (and vessels)] even though it has a more modest sound than the original title. The titles of the four volumes have been selected on the basis of their content.

The problem of correlation has been the rock on which many textbooks written by multiple authors have foundered. If the various parts do not follow a logical sequence; if some of them are disproportionately long or short; if some are written by obscure authors of poor talent while others are the result of the work of well-known authorities; then the whole encyclopedia has no value.

In order to obviate these possibilities, the following steps are necessary: (1) the authors selected should be among the best, (2) each should receive a carefully selected and clearly outlined job, and (3) the editors should be able to refuse, abbreviate, or send back for correction any received text. Therefore, courage, patience, and hard labor are necessary to ensure a successful literary production.

The outcome of the work depends to a large extent upon the selection of authors. Well-known authors who have left a mark in the history of cardiology are the natural choice. However, they may be reluctant to undertake a major task and, moreover, may not be able to ensure continuity on account of their age. A compromise may be represented by asking these authors to prepare the text in collaboration with one of their associates. The associate would be the natural choice for any future revision of the text. However, a different author may entirely revise a chapter at a future date.

Science is international. If a truly objective work is to be published, authors of all nationalities should be asked to contribute. The recent tremendous progress of cardiology in the North American continent may require that a majority of the authors be selected in the United States and Canada However, numerous contributors have been selected from England, continental Europe, Mexico, South America, Africa, and Asia, so that a truly "global" representation of cardiology may result.

How much of the text should reflect generally accepted viewpoints; how much should present new ideas still awaiting confirmation? This problem cannot be solved in a general way. The viewpoint of the editor is that an intermediate position should be preferred. Texts reflecting only generally accepted views might render the entire work obsolete within a few years. On the other hand, many new viewpoints cannot withstand the test of time and are gradually discarded. Whatever the error, whether in the sense of conservatism or in that of progressivism, a loose-leaf type of work may remedy it more rapidly than any standard type of volume.

The Editorial Board has been selected with great care according to these viewpoints:

1. Inclusion of a few authorities which would help in laying down the directives of the work.

2. Selection of persons with diversified knowledge (physiology, pathology, pediatrics, surgery, etc.), so that all fields may be covered by competent editors.

3 Choice of as many young scientists as possible, in order to have a high potential of enthusiasm, criticism, and working capacity.

The final product will reveal whether these directives are sound and have been followed as closely as possible.

The publication of this encyclopedia was made possible by the continued support of the American College of Cardiology through the action of its board of trustees, by generous contributions of five pharmaceutical houses, and by the warm collaboration of the McGraw-Hill Book Company, Inc., Blakiston Division.

ALDO A. LUISADA
Editor in Chief

cardiology. It is likely that a four-volume, 5,000-page encyclopedia would represent the optimal size. However, practical considerations indicate a more limited approach for the first version. Therefore, a four-volume, 3,600-page size is considered for the first edition, even though gradual revision and extension over the following ten years will probably increase the size to that previously mentioned.

Several titles have been considered for this encyclopedia. The one preferred by the editor, *Encyclopedia of Cardiology,* has been discarded for fear of discouraging prospective readers. The more modest title which has been selected—*Cardiology*—emphasizes the main scope [knowledge about the heart (and vessels)] even though it has a more modest sound than the original title. The titles of the four volumes have been selected on the basis of their content.

The problem of correlation has been the rock on which many textbooks written by multiple authors have foundered If the various parts do not follow a logical sequence; if some of them are disproportionately long or short; if some are written by obscure authors of poor talent while others are the result of the work of well-known authorities, then the whole encyclopedia has no value.

In order to obviate these possibilities, the following steps are necessary: (1) the authors selected should be among the best, (2) each should receive a carefully selected and clearly outlined job; and (3) the editors should be able to refuse, abbreviate, or send back for correction any received text. Therefore, courage, patience, and hard labor are necessary to ensure a successful literary production.

The outcome of the work depends to a large extent upon the selection of authors. Well-known authors who have left a mark in the history of cardiology are the natural choice. However, they may be reluctant to undertake a major task and, moreover, may not be able to ensure continuity on account of their age. A compromise may be represented by asking these authors to prepare the text in collaboration with one of their associates. The associate would be the natural choice for any future revision of the text. However, a different author may entirely revise a chapter at a future date.

Science is international If a truly objective work is to be published, authors of all nationalities should be asked to contribute The recent tremendous progress of cardiology in the North American continent may require that a majority of the authors be selected in the United States and Canada However, numerous contributors have been selected from England, continental Europe, Mexico, South America, Africa, and Asia, so that a truly "global" representation of cardiology may result.

How much of the text should reflect generally accepted viewpoints; how much should present new ideas still awaiting confirmation? This problem cannot be solved in a general way. The viewpoint of the editor is that an intermediate position should be preferred. Texts reflecting only generally accepted views might render the entire work obsolete within a few years. On the other hand, many new viewpoints cannot withstand the test of time and are gradually discarded. Whatever the error, whether in the sense of conservatism or in that of progressivism, a loose-leaf type of work may remedy it more rapidly than any standard type of volume.

The Editorial Board has been selected with great care according to these viewpoints:

1. Inclusion of a few authorities which would help in laying down the directives of the work.

The range of normal blood pressure

BLAS MOIA

The values of normal arterial pressure undergo notable modifications during the course of life and according to the mode of life of each individual

In the healthy *new born*, the average arterial pressure is around 55/40 mm Hg (Bricker and Connell) but rises rapidly in the days following birth Reis and Chaloupka observed that the systolic pressure rose from an average of 43 mm during the first day of life to 78 mm at the age of 10 days, the greatest elevation apparently occurring during the first 3 days Between the first month and the first year of life, the pressure continues to rise, although not so rapidly, attaining an average of from 59/30 to 95/58 mm Hg at the end of the first year of life From 5 to 16 years of age, the average pressure values are from 92/52 to 122/62 mm From this point on, opinions begin to differ. Some authors, especially Alvarez et al, find a marked elevation during *puberty and adolescence*, followed by a diminution in later years, the average systolic pressure being 127 mm at 16 and 118 mm at 30 in males, and 118 mm at 16 and 111 mm at 24 in females The greater rise in men could perhaps be explained by the fact that boys mature between the ages of 16 and 19 and are stronger and more active at that age than girls, who mature at an earlier age

Nevertheless, recent statistics (such as those of Master et al. and Hamilton et al), based on more exacting techniques of pressure registration, do not confirm the existence of such variations They show that after the age of 16, the average arterial pressures, systolic as well as diastolic, continue to rise slowly and regularly with age, although after 50 years of age the systolic pressure rises more rapidly. This point is illustrated in Table 12-1 from Master et al., made with measurements taken in 15,700 persons of both sexes between the ages of 16 and 65, selected at random among 74,000 industrial workers. The average figures are somewhat lower than those of Goldberg and of Russek et al., and a little higher than those of Robinson and Brucer, although the figures are practically parallel

In the elderly individual, especially after 65 years of age, the average systolic pressure is *above 150 mm Hg*, arriving at around 165 mm between the ages of 85 and 95. However, the variations of the diastolic pressure are much *smaller*, the average being 90 mm The changes are probably due to atherosclerosis of the aorta Nevertheless, Master et al., studying elderly persons without evidence of cardiovascular disease, find that the average systolic pressure does not continue to rise in males after the age of 65 or in females after the age of 70 The pressure remains constant until the age of 85 and then declines Between the ages of 70 and 74, the average values were 14 mm higher in women than in men, tending to become equal at the age of 90 In contrast, the diastolic pressure shows no difference in regard to sex and falls slightly after the age of 85.

It is evident that the behavior of these variations of pressure is influenced by sex as well as by age Indeed, with a few discrepancies, almost all statistics show that, until around the age of 40, the arterial pressure, and especially the systolic pressure, is somewhat lower

SOURCE: Master et al.

in females than in males, while later it tends to become somewhat higher, although without significant differences. It must be noted that this rise in arterial pressure according to age does not present the same degree in all individuals. *There are persons in whom the pressure rises very little during different decades of life*, presenting, even in old age, relatively low figures (for example 120/70), while others may have a rapid rise and may have values in excess of 150/100 mm Hg at the age of 50

There have been attempts to explain these differences in the behavior of arterial pressure on the basis of constitutional, racial, environmental, and other factors, but no definite conclusions have been drawn on this subject Indeed, other than genetic and hereditary factors, which seem to be well substantiated, there is very little agreement on the numerous other elements which have been postulated For example, no one has been able to demonstrate the existence of a definite psychic hypertensive personality *Stress*, which has been accepted as an etiologic factor of hypertension by some investigators, is not accepted by the majority. There does not seem to be convincing evidence that *occupation* per se and *environmental physical factors* play a significant role in the elevation of arterial pressure.

The importance of the *racial factors*, especially in reference to the characteristics of the pressure behavior in Negroes of different countries, Chinese, etc., cannot be seriously considered until new statistics have been tabulated with uniform criteria and taking into consideration state of nutrition, body weight, etc.

It is quite evident that blood pressure tends to be higher in persons of heavy build. According to the statistics of Master et al., the difference in the average systolic pressures between very light and very heavy individuals is greater than 10 mm, the diastolic pressures following an almost parallel course. These differences are more notable in females, particularly after the age of 40. On the other hand, they do not have any relationship with the *height* of the individuals.

These variations may or may not have real significance, but it is important to decide when the values found for a determined age cease to be physiologic and become pathologic The anarchy which reigns with respect to the evaluation of all these factors is impressive Table 12-2, based on a careful analysis of 33 publications, gives an idea of the situation Adding still more to the confusion is the difference in criterion of different authors in regard to the reading of the diastolic pressure, technical errors, etc.

Obviously one of the least acceptable criteria is the evaluation of the systolic pressure only There may exist an abnormal increase in the systolic pressure with a normal or low diastolic pressure; this may occur without hypertensive disease (i e., without increase in peripheral resistance), in aortic insufficiency, hyperthyroidism, complete AV block, and atherosclerosis of the aorta and its large branches However, in the latter condition, there may be a rise in the diastolic pressure, although generally less marked On the other hand, an abnormal rise in diastolic pressure in rare cases may not be accompanied by a systolic rise, and should be considered as evidence of arterial hypertension

It is widely accepted that the upper limit of norm is 150 mm Hg for the systolic pressure and 90 mm for the diastolic, but this absolute dividing line between normal and abnormal pressures cannot be considered as valid any longer It is evident that a figure of 150/90 would be much more abnormal for a girl of 20 than for a woman of 50 It is necessary then to allow a greater elasticity to this dividing line and to consider as normal not only what is most perfect, but also *what is the most frequent* For example, we do not frequently find definitely elevated blood pressures in the young individual and, therefore, in such a circumstance any elevation should be considered as indicating a secondary hypertension. On the other hand, figures of 140/90 or even more are found (Master et al.) in 40 per cent of individuals between the ages of 45 and 49, and in 60 per cent of persons between 60 and 64. Figures around 150/100 or more are found in 20 per cent of individuals between 40 and 45 and in 35 per cent of those from 60 to 64.

Pickering (1955b), whose statistics support the concept of Master et al., believes that the differences between the highest and lowest pressures are quantitative and not qualitative; there are differences of degree and not types. Consequently, there cannot be "justification for a division of arterial pressures into normal and pathologically high, and it is the height of the pressure that matters." Sharing this opinion are Kagan et al., who, after reviewing results of the first 4,499 carefully studied cases in Framingham, state that "there was no evidence in the distributions or in the correlations with x-rays and electrocardiographic abnormalities to suggest a sharp line of demarcation between normal and abnormal blood pressures" These concepts, interesting as they may be, should nevertheless be considered with caution. They demonstrate the distribution of pressure values in men and women of different groups according to age but *do not exclude that this large percentage of individuals, whose*

arterial pressure tends to be greater than 140/90, are actually moderately hypertensive and do not indicate with certainty that they are simply presenting the result of a physiologic aging process In order to overcome this objection, Master et al. suggest considering as abnormal *the sum of the mean values plus the double of the standard deviation,* but this criterion, although statistically acceptable, is arbitrary, since there is no sharp division between the levels of clearly normal and clearly abnormal pressures. Therefore, it is necessary to complement the criteria of frequency with those of morbidity and mortality, and to try to find for a determined age group which pressure levels correspond with persons who have not developed clinical manifestations of hypertensive disease or arteriosclerosis and who have no decrease of their life expectancy This study would be more important from a medical and a social viewpoint but is very difficult to translate into reality Everyone who has been able to follow the evolution of hypertensive individuals for more than 20 or 25 years has seen patients with very high blood pressures who continue to live with few or no clinical manifestations while others, with less marked pressure elevations (sometimes below 180/110), rapidly suffer the consequence of hypertensive disease and die as a result of its complications

The statistical studies of insurance companies demonstrate an increase in mortality as soon as the pressures begin to rise, even if only to a slight degree, above the limits which are now commonly accepted as normal But this criterion, useful from their viewpoint, is not necessarily indicative that the increase in mortality is a direct consequence of the pressure rise, since they do not take into consideration the morbid factors which have contributed to this rise and which may themselves be responsible for death The importance of the vascular disease which usually accompanies, but may not be secondary to, the blood pressure rise should not be neglected

Even admitting the existence of these exact demarcation levels, the situation is complicated by the fact that many persons, without going beyond the maximum limits which are commonly considered as normal, have pressures which are high for their age. Others, whose hypertension is of the so-called "labile" or "transitory" type, may be, under certain circumstances, above or below the normal limits Such variations in pressure may be observed during a single physical examination in which the reading is repeated at brief intervals or in examinations done at different hours of the day or on different days and under different circumstances. Since the observations of Addis, it has been customary to call *basal pressure* that which is found as soon as the patient awakens and before he arises from bed or takes food. According to Alam and Smirk, "basal pressure" is the pressure found in conditions similar to those in which a basal metabolism test is done, while *casual pressure* is that found without previous preparation and during the normal daily activities. The difference between basal pressure, which is always lower, and casual pressure, represents the supplementary fraction which depends upon emotional stress, physical activity, or suprabasal metabolic activity of the patient in a given moment

The significance of these findings in regard to their relation to normal arterial pressure range has not yet been properly clarified Some authors consider that fluctuations of less than 15 to 20 mm Hg due to physical fatigue are normal and physiologic. On the other hand, others believe that short periods of sustained elevation of the arterial pressure should be considered as early manifestations of hypertensive disease

The Anglo-American Committee on Standardization of Blood Pressure Readings, in its first report, warns against reaching any definite conclusion in regard to the blood pressure of any individual unless numerous pressures have been taken in successive visits, because frequently the first reading is much higher than the following, owing to the patient's apprehension and nervousness. Smithwick, as well as Perera, insists on the necessity of taking basal pressures for statistical studies. "The arterial pressure, as it is casually recorded is of little significance in determining trends or prognosis" Nevertheless, this criterion is not without fault there are patients with obvious clinical evidence of hypertensive disease who, after some days or weeks of bed rest, and especially if they are isolated from their usual

environment, have such a marked lowering of both casual and basal pressures as to be found normotensive.

It is probable, although not definite, that arterial hypertension is less reversible in patients whose pressure elevations are more fixed. But, although it is evident that the level of arterial pressure is not the only factor which determines the severity of the hypertensive process, it cannot be denied that the casual hypertension which the patient suffers during at least 14 to 16 hr during the day, should have unfavorable repercussions on his circulatory system, even though the pressure becomes normal during rest.

The most valuable information with respect to the significance of this transitory type of hypertension is that given by statistics gathered by Levy et al (1944), based on pressure readings of 22,741 officers of the U.S. Army, 84 per cent of whom were under observation for 5 to 19 years, 38 per cent from 15 to 19 years, and 6 per cent for 20 years or more. Only those patients were considered whose first examination revealed a pressure of 150 mm or more systolic and at least 90 mm of diastolic pressure, but in whom was found a pressure drop either during the same or in a subsequent examination It was observed that the frequency of these exaggerated pressure variations increased with age, following a uniform line which began with 5 9 per cent between the ages of 25 and 29 and ended in a plateau with 18 6 per cent between the ages of 50 to 54 The age group percentages of persons in this group who developed permanent hypertension varied between 2 4 per cent between the ages of 25 to 29 and 48 per cent between the ages of 55 to 59, in contrast to 0 to 5 per cent and 14 9 per cent respectively for the control group

It may be said that permanent arterial hypertension develops 3 5 times more often in individuals with labile or transitory hypertension than in others It is interesting that the development of a permanent arterial hypertension was observed both in cases with small pressure fluctuations and in cases with large ones. In this sense, it is significant that even a slight, isolated systolic hypertension or a transitory rise of the diastolic pressure above 100 mm is the forerunner of permanent arterial hypertension Later, these same authors observed that, in addition to transitory hypertension, tachycardia and excessive body weight are important in the development of a permanent hypertension, the *probabilities increasing if* two of these factors exist together and especially if all three are found present Nevertheless, Hines (1940), discussing the significance of pressor tests, reaches the conclusion that the type of hyperreaction which is accompanied by tachycardia and *systolic hypertension*, and which is due basically to an increase in cardiac output, is not characteristic of arterial hypertension in any of its states. On the other hand, that which is accompanied by *diastolic hypertension* (with or without systolic hypertension) and without significant tachycardia, apparently predicts the *development of* a sustained arterial hypertension in more than 50 per cent of the cases.

In regard to the already mentioned statistical data, there are contradictions which *depend* not only upon the *different criteria of interpretation* of each author but also on the different conditions and methods of examination used. Nevertheless, *considered as a whole*, these statistics *clearly indicate that an absolute line of demarcation cannot be fixed between normal and abnormal blood pressure in man* Therefore, each case should be considered individually, taking into account not only the clinical picture, but all the above-mentioned factors which may be acting.

Although hypertension is only a *sign of the* disease as long as *the cause* is not known, one must be guided by pressure readings in order to judge if a hypertensive state exists or not. There is no doubt as to the definition of normal or abnormal if two adult individuals present arterial pressures of 120/80 and 200/120, *respectively*. On the other hand, doubt may arise when, as the person advances in age to about 50, it is found that he has permanent or transitory readings oscillating in the borderline zone around 150/100 *If, at this time*, an exhaustive clinical examination of the patient does not provide other *evidence* of hypertensive disease, it is wise not to consider him hypertensive, as yet Although *it is* more common that persons of this group develop in time more significant hypertension, it is not necessarily *always* true that an individual in

the group will do so. It is evident that there is a high percentage of patients who for many years remain free of vascular and visceral complications while their pressure level does not rise significantly, and the life expectancy is not shortened. Consequently, before labeling one of these patients "arterial hypertensive," with all the unhappy psychologic effects which may follow, the physician should submit his patient to a careful and prolonged clinical observation, advising him as to the most appropriate mode of life but without subjecting him to uncomfortable or harmful restrictions or unnecessary therapeutic measures.

2

Psychic factors in essential hypertension

PHILIPPE V. CARDON, JR.

Before considering the psychic factors involved in hypertension and hypertensive heart disease, it is advisable to ask what is meant by psyche and psychic factors

BASIC CONCEPTS

The function of all living *organisms can be* altered by changes in the environment Organisms with well-developed central nervous systems often perceive environmental changes at a distance with the organs of sight, hearing, and smell The brain then decides whether something should be done about them If so, heretofore minute physical changes within the organisms, induced in the brain by the environmental changes, may trigger gross *energy* transformations in other parts of the body Whether the brain's evaluative function is "thinking" or "instinct," "conscious" or "unconscious" is irrelevant here The entire sequence consists only of physical (material) phenomena The word "psyche" is a useful abstraction to denote an aspect of the brain's physical function, just as "circulation" denotes the function of heart and blood vessels The word "psychosomatic" is clear in its *intent* but inaccurate in its implication that the psyche is not part of the soma

It is well established that the brain (psyche) can cause changes in the functions of the rest of the body through three mediating systems the nerves to skeletal muscles, the autonomic nervous system, and the endocrine system "Psychosomatic" inquiry tries to define and quantify these changes in man and to define their relevance, if any, to disease and death

Historically, interest has focused primarily on the bodily changes that occur in psychically troubled people. Changes postulated to be harmful to them are usually thought of as inappropriately sustained emergency responses—inappropriate in the sense that such individuals habitually perceive minor challenges as serious threats. However there is [illegible]

[illegible] everyday life as harmless Neither can one assume that physiologically harmful adjustments to environmental stimuli necessarily stem from "sick," "abnormal," or "neurotic" interpretations of the stimuli.

A minority of "psychosomatic" phenomena are best explained as symbolic expressions of feelings or impulses, presumably unconscious makeshift "solutions" of neurotic conflicts. *The majority, of which acute neurogenic hypertension is an example, cannot be satisfactorily explained in this way* They are phenomena of which the psyche *is completely* unaware They frequently seem to make more sense viewed as *manifestations of adjustments* which have favored *survival* of the species during evolution Such a *view does not* necessarily imply that the adjustments *promote* good health beyond the child-bearing *years, that they* are useful in civilized life, or that *epiphenomena* of useful adjustments are useful per *se*

PERSONALITY AND BEHAVIOR

It has been the usual experience of psychiatrically oriented investigators that as a group [illegible]

[illegible] Weiss et al). Patients have been characterized by different observers as having neurotic traits, excessive dependency needs, poorly handled feelings of hostility, difficulties in interpersonal relationships, excessive rigidity, etc They tend to be less assertive, less at ease and more uncertain in their relationships with other people, easily *injured* but fearful of hurting others. Efforts *to* define a

characteristic "personality profile" always and exclusively present in patients with hypertension have been unsuccessful. Some observers reporting group differences also report a small minority of hypertensive patients who, by the same criteria, have normal personalities.

That chronic illness of any sort may accentuate latent personality defects probably does not account for the observed differences. In one study, hypertensive persons were matched with neurotic patients without hypertension or other of the disorders commonly termed "psychosomatic," and with patients with chronic "nonpsychosomatic" diseases, such as malignancy, anemias, chronic pulmonary infection, etc. Each group was rated as to the extent to which the traits of anxiety, hysterical symptoms, obsessive-compulsive behavior, depression, subnormal assertiveness, and impulsiveness were thought to be present By these criteria, *the entire group of hypertensive persons differed significantly from neurotic patients in that obsessive-compulsive and subnormal-assertiveness traits were more prominent.* They differed from the patients with other chronic illnesses in greater prominence of all traits except impulsiveness There was no significant difference among hypertensive patients with "neurogenic," "renal," or "endocrine" hypertension (Saslow et al)

Retrospective histories, which, of course, cannot be accepted at face value, usually indicate that the personality features antedate known hypertension Two separate studies showed that college students whose blood pressure was high on routine physical examination differed significantly in some personality features from those with low blood pressure (Hamilton; Harris et al.). These studies were suitably controlled and any bias of foreknowledge was eliminated. In the latter study, the psychologic criteria which enabled the investigators correctly to predict a subject's blood pressure category with significant frequency were derived from clinical experience with hypertensive patients. If such young people are more likely to develop essential hypertension, it follows that detectable differences in personality antedate the onset of hypertension. Studies like those cited do not establish a causal relationship between the psychic features observed and essential hypertension.

SYMPTOMS, SIGNS, AND OUTCOME

Most of the early symptoms of essential hypertension—headache, dizziness, fatigue, insomnia, musculoskeletal pain, exertional dyspnea, etc—seem definitely to be affected by psychic factors. Early observers pointed out the similarity between these symptoms and those encountered in patients with psychoneurosis (Riseman et al.; Ayman et al., 1931). The frequent lack of correspondence between symptoms and blood pressure level is well known At least half of hypertensive patients report the disappearance or lessening of these symptoms upon the establishment of a supportive relationship with the physician, despite the persistence of high blood pressure.

Variations in blood pressure level can frequently be correlated with variations in a patient's life situation Times of strained relationships with other people, particularly when the patient is continually angry, seem most often associated with rises in blood pressure. Periods of relative tranquility are often associated with lower blood pressure It is obviously difficult to control adequately such observations. It is doubtful whether reported studies can settle this question in the physician's mind any more effectively than his own clinical experience.

The *course* of hypertensive disease is probably often significantly modified by psychic factors The return of blood pressure to normal can reasonably be regarded as a favorable alteration of the course, and the development of the malignant phase as an unfavorable acceleration. As to *improvement*, in one psychiatrically oriented medical treatment program, in which antihypertensive drugs were not used, blood pressure returned to normal in about 10 per cent of patients (Wolf et al). These patients were considered, in retrospect, to have succeeded in making favorable basic alterations in their manner of dealing with life's problems More convincing, at the start of treatment, it had been predicted, on the basis of a prognostic index almost entirely psychologically and sociologically derived, that these particular patients would do well As to *worsening*, in a study of 12 patients who developed grade 4 retinopathy, it was concluded that in all patients the malignant phase was immediately preceded by, and continued to

develop in, life situations that were particularly difficult and threatening (Reiser et al). Furthermore, in some cases, resolution of difficulties was accompanied by a fall in blood pressure and disappearance of papilledema.

MECHANISM

What sorts of responses to psychic stimuli are similar to conditions present in resting hypertensive persons? The following brief discussion is a statement of the author's views on the significance of available data.

Hemodynamic Changes The blood pressure usually rises in response to psychic challenge or threat. Mean blood pressure may rise as much as 50 mm Hg within 30 sec In normotensive persons, the average rise is about 10 mm Hg, in hypertensive patients, about 18 mm Hg Expressed as percentage of [illegible] than systolic

Such acute rises are mediated principally by the sympathetic nervous system and adrenal medulla The rise is usually a result of *increased cardiac output with a fall in total peripheral resistance ("output" pattern)* Heart rate and flow to skeletal muscle increase, effective renal plasma flow decreases (by as much as one-third), as does flow to the skin of the extremities This type of pressor response is similar to that observed after moderator nerve interruption in man, after administration of epinephrine, and in frightened animals (Cannon's "fight-or-flight" response)

Though it occurs most frequently, this is not the only hemodynamic pattern in acute neurogenic hypertension Peripheral resistance may rise concurrently, and in less than one-third of instances the psychically induced rise in blood pressure is caused *solely by increased peripheral resistance ("resistance" pattern)* Cardiac output, pulse, and skeletal muscle blood flow do not rise (or may decrease), while flow to the kidneys and extremity skin decreases as usual Infusion of norepinephrine or electrical stimulation of certain areas in the frontal and temporal lobes of the cerebral cortex produces a similar pattern

In both patterns, the average rise in blood pressure is of about the same magnitude, as is the decrease in renal plasma flow, which usually persists for an hour or more after the blood pressure has returned to normal.

Naturally occurring output and resistance patterns are not such distinct entities as the artificial analogues induced by infusing epinephrine or norepinephrine For instance, neither hormone alone causes both cardiac output and resistance to increase—a not unusual natural occurrence. The frequent fall in diastolic blood pressure caused by epinephrine and the bradycardia caused by norepinephrine are rarely observed during psychic pressor responses.

The foregoing considerations indicate that the hemodynamic situation during acute neurogenic hypertension may closely resemble that seen in resting hypertensive patients. It is probably incorrect, however, to view essential hypertension as an inappropriately sustained neurogenic response of the resistance type For instance, hypertensive patients frequently respond to psychic stimuli with output patterns. Though some studies disagree, in the largest reported series, normotensive and hypertensive persons do not differ in pattern frequency (Wolf et al)

In the cold-pressor test, similarly, the more frequent pattern is of the output type in both normotensive and hypertensive persons. If an excessive rise in blood pressure in response to pain indicates a predisposition toward essential hypertension, there is no present basis to believe that resistance reactors are more or less vulnerable than output reactors

There is better evidence, which need not be detailed here, that the high peripheral resistance in established essential hypertension is maintained, at least in part, by factors other than increased sympathetic activity The most direct evidence of this to date is that about two-thirds of hospitalized hypertensive patients do not excrete excessive amounts of epinephrine or norepinephrine in the urine, while about one-third of them do (von Euler et al) The untested possibility remains that in everyday life, most hypertensive persons, rather than a minority of them, undergo unusually frequent and sustained episodes of sympathetic discharge for psychologic reasons and that, over a period of years, these episodes in turn result in the activation of other pressure-sustaining mechanisms

Changes in Vascular Reactivity. The conjunctival vessels of hypertensive patients are unusually sensitive to the constricting action of topical epinephrine and norepinephrine (Lee et al). In normal persons, sensitization can be induced acutely by psychic stimuli, and has been observed during the resting state on days when the subject's life situation was unusually trying (Ostfield et al) It is not known whether the mechanism of sensitization in the three circumstances is the same.

Changes in Renal Function. The role of altered renal function in the pathogenesis of hypertension is still unclear It is not known whether the neurogenic renal vasoconstriction which may follow

psychic stimuli can activate any of the several renal mechanisms suggested. There is some information, however, on the effects of psychic factors on water and sodium excretion The relevant reported abnormalities in hypertension are in the direction of the retention of water and sodium. Psychic factors often cause water and sodium retention.

THERAPEUTIC CONSIDERATIONS

The clinical and experimental information briefly reviewed above is incomplete and inconclusive Though many observers would prefer to reserve judgment pending better evidence, the practicing physician cannot do so, his patients need treatment *now* It seems more likely than not that psychic factors significantly contribute to the genesis and affect the course of essential hypertension, if so, what can one do about it?

It is possible that any benefit conferred by sympathectomy, ganglionic blocking agents, or centrally acting drugs, such as *reserpine* and *Apresoline,* results from a partial insulation of the psyche, either from the environment or from the rest of the body Certainly, the services provided by the physician (diagnosis, explanation, treatment, continued interest and support) are also potent and direct forms of psychotherapy. The question arises whether some more explicit effort is worthwhile to help the patient to think and act differently While many patients and physicians are convinced that it often is, acceptable scientific validation of this conviction does not exist as yet. The following suggestions are offered to physicians because they seem reasonable in the light of present knowledge.

Initial Evaluation. At your first contact, begin to look for clues to the question, "What *sort of a person* is this patient?" All doctors do this more or less automatically The more you do it consciously and thoughtfully, the better the patient's chances of getting the greatest possible help. It need not require more time, but rather a heightened awareness of the *whys* as well as the *whats* of the patient's discourse and behavior.

It helps to ask yourself *specific questions* With regard to your relationship with the patient, these might include· What influences other than his "chief complaint" led him to consult me at this particular time? Why did he pick me? What does he expect from a doctor? What do I expect of him? Of myself in this situation? Assuming that he wants to make a good impression on me, what does his present behavior tell me about what he expects of himself and of others? What things about him do I like or dislike?

One might characterize such inquiry as an attempt to become unusually aware of this human being's "style" in his dealings with you, and of your reactions to it. Such awareness helps you to plan a treatment program which the patient will accept. Equally important, it is an appropriate starting point in your assessment of the psychic factors in his illness. The rough spots in his relationship with you are usually prototypes of problems he has faced for many years in his relationships with others.

Allow personal material to emerge early in the initial interview. Where appropriate, phrase some questions vaguely: "Do you have any explanation for this illness? Tell me about your work. How are things at home?" etc If an answer seems irrelevant, postpone any interruption long enough to estimate why the answer is important to the patient

Ask supplementary specific questions, pertinent to psychic symptomatology, as a part of the initial interview. The patient's handling of the question "Have you ever had a nervous breakdown?" often yields information about his understanding of, and attitude towards, psychic illness, insanity, psychiatrists, etc. "What sorts of bodily symptoms do you get when something upsets you?" will elicit information about his awareness of emotions, insight, and probable reaction to any subsequent psychosomatic formulations of symptoms. It may also reveal a common point of departure for subsequent discussions

The early timing of such inquiry is important To postpone it for a "second round," perhaps after laboratory results are available, may raise unnecessary obstacles. The patient may correctly or incorrectly paraphrase the physician's actions thus "I can't find anything seriously wrong—it may all be in your mind I don't talk about these things with most of my patients—i e , those with 'legitimate' disease " If the patient has set the pace of the early part of the initial interview and relevant

psychic material has clearly emerged, then it is the physician who restores balance, conservatism, and the assurance that no possible treatment will be overlooked, by obtaining a complete medical history and appropriate tests.

Continuing Treatment. The most appropriate plan of psychotherapy may in rare cases be a tacit understanding that psychic considerations are totally irrelevant to the present problem. This may be true either of patients with little intelligence or capacity for insight, or of patients who probably are painfully aware of severe problems in adjustment, or of deviations from social norms, but would really prefer to have the physician "mind his own *business*"

At the other extreme, a few hypertensive patients can most appropriately be treated by a psychiatrist, if one is available Practically, these are usually patients who will accept the idea, are intelligent, can afford it, and are aware of relatively severe psychic symptoms. The psychiatrist can be of help in many more cases in the role of consultant. Psychiatric referral should convey the message, "We need an expert opinion on this aspect of the problem," rather than "What you need for *your* trouble is a psychiatrist." Whenever possible, you and the psychiatrist should be familiar with each other's individual interests, methods, and capabilities An ideal arrangement, when geography permits, is for the psychiatrist to come to your office and interview the patient in your presence.

Most hypertensive patients fall between the two extremes just discussed When your preliminary evaluation is complete, define the problem for the patient and explain his hypertension to him in terms which you think he can accept Propose further discussions of some of his problems as a frequently successful means of reducing symptoms Encourage him to look at the life settings in which symptoms arise. Make it clear that the symptoms are not imaginary, that they are not caused by high blood pressure per se, and that when you say "troubles can give rise to such symptoms," you are simply saying that he is human The patient may quickly see relationships between symptoms and problems but prefer not to admit this to you A patient often views psychosomatic interpretations as insults, not only to himself and his family, but to physicians consulted in the past who have not raised such issues.

There is a formidable list of medication that might seem indicated for headache, fatigue, backache, flatulence, constipation, nervousness, and insomnia. The patient should at least be exposed to the idea that there may be better ways to attack symptoms. His reaction to this idea is one index of what one can hope to accomplish by "psychotherapy" prescribed as such. One tries to hold symptomatic medication to a minimum, thus registering a vote of confidence in the patient's ability to change, without causing useless distress or expecting more of the patient than he can accomplish. If antihypertensive drugs are not urgently indicated, there are good reasons, to be given later, for not using them immediately.

There can be no adequate attempt in this discussion to convey what one "does" with personal material as it emerges. The physician's major role here is to ask for information and to define areas of conflict. Specific advice about the patient's conduct in a difficult situation usually does more harm than good.

Skill in this area improves with experience and training. Most physicians are aware of a lack of both The physician may thus be at an unnecessary disadvantage when the patient says directly or by innuendo. "You aren't helping me enough" In feeling defensive about the justice of the accusation, the physician may miss the point, namely that the patient thinks he has limitless healing powers, but is withholding them because of the patient's unworthiness The physician's limitations can be used as an impetus towards an important goal—that the doctor-patient relationship, which so frequently recapitulates that of parent and child, becomes one between two adults "side by side" The physician who is jealous of his power will only reinforce the patient's habits of suspicious, hostile, dependent compliance

Within a few weeks or months, symptoms may have diminished greatly, but the hypertension is usually unaltered The patient feels that he is beginning to repeat himself. The physician has a better understanding of the patient's problems but does not see what more he can do to help the patient meet them. Th

psychic stimuli can activate any of the several renal mechanisms suggested There is some information, however, on the effects of psychic factors on water and sodium excretion. The relevant reported abnormalities in hypertension are in the direction of the retention of water and sodium. Psychic factors often cause water and sodium retention.

Pathology in systemic hypertension

SIMON KOLETSKY

The principal pathologic lesions in patients with long-standing hypertension occur in the heart, the peripheral vascular bed, the kidneys, and the brain

The *heart* is enlarged, mainly because of hypertrophy of the left ventricle The organ is increased in weight, usually to levels of between 400 to 600 Gm, but even the latter figure can be exceeded There is an increase in width of the left ventricular wall, which usually measures from 2 0 to 3 0 cm in thickness, and this is associated with enlargement and prominence of the trabeculae and papillary muscles (Fig 12-1) Initially, the cardiac hypertrophy involves principally the outflow tract, from apex to aortic orifice, and this often appears considerably lengthened Two forms of hypertrophy are described, concentric and eccentric In the former, the walls are thick and the chambers reduced in size, while in the latter, increased weight is associated with enlarged chambers

The increase in cardiac weight is probably due solely to *increase in size or thickness of the individual muscle fibers* The sarcoplasm is increased in amount, and the nuclei become enlarged and show blunting of their ends Apparently the fibers do not tend to become uniformly enlarged. No abnormality other than increase in size of the fibers is commonly seen, although there may be such retrogressive change as vacuolization or fatty degeneration of the muscle cells Interstitial fibrosis in the absence of significant narrowing of the coronary arteries is not common

The left ventricular hypertrophy in hypertension is attributed to the increased resistance offered by the peripheral vascular bed to discharge of blood from the chamber. According to the present concept, *the hypertrophy is preceded by dilatation of the chamber* resulting from retention of blood because of the initial inadequate output. Roberts and Wearn thought that the limits of compensation by hypertrophy are probably related to blood supply. While the number of capillaries remains the same during hypertrophy, they are spaced farther apart as the muscle fibers enlarge, and thus have to supply a larger mass of muscle from a greater distance. Both factors hamper adequate exchange of oxygen and metabolic

Fig. 12-1. Cardiac hypertrophy in a patient with hypertensive heart disease The heart weighed 600 Gm Note thick left ventricular wall, together with prominence of papillary muscles and trabeculae.

patient can be warned in advance that this often happens. The warning helps the patient to maintain a realistic view of the physician as an experienced but still limited human being.

In the over-all plan of treatment, this is an appropriate time to initiate antihypertensive drugs, if they seem indicated, the patient having been told previously that they may be necessary. By this time, much helpful "baseline" information is available. In addition, by delaying antihypertensive drugs, the physician indicates more clearly than he can with words the chronic nature of the disease and his conviction that hypertension in itself is not a medical emergency. When started, the medication can represent to the patient a long-term means of keeping the blood pressure within safe limits. He deserves to know that some situations and reactions can cause his blood pressure to be higher or lower, but "specific" medication prevents the useless hardship of regarding every crisis as a threat to life. He gains courage in his efforts to abandon old patterns of resentful dependency. At the same time, he is forced to avoid the temptation to take unfair advantage of others by asserting his disease, rather than himself, when conflicts arise.

Following the periods of initial enthusiasm and subsequent disenchantment, physician and patient can settle into a supporting, hopeful, conservative relationship. Presumably, any psychic benefit to the hypertension is independent of the declared goals of therapy. The door is open for continuing discussion of psychic problems. The physician is fully justified in charging for the time spent in such discussions. The patient must understand that the goals of greater self-esteem and loss of useless anxieties are, by themselves, realistic and worthy.

the marked predilection of the kidneys of hypertensive patients for the vascular lesions. In contrast to the belief that hypertension causes the vascular disease, it has been suggested that *renal arteriolar disease is the primary lesion and serves to initiate the hypertension*

The vascular lesions of *chronic hypertension* have been described in detail by Moritz and Oldt. The most common change is intimal hyalinization, consisting of subendothelial deposit of homogeneous acidophilic material, which appears to represent an infiltration or expansion of the ground substance between the media and the endothelium This is commonly associated with either fatty or hydropic degeneration The hyalin is disposed as a circumscribed subendothelial plaque, or forms a subendothelial collar of uniform thickness, or can be annular and of irregular thickness It often involves the internal elastic membrane and may produce swelling, disruption, or obliteration of the lamellae Marked hyaline change may result in considerable narrowing of the lumen of the vessel

Another frequent lesion is endothelial hyperplasia, especially in vessels over 50 μ in diameter This change can also produce substantial reduction of the vessel lumen. The hyperplastic endothelial cells tend to become spindle-shaped and resemble connective tissue cells. Commonly, the proliferative change is associated with increase in elastic fibers between the newly formed endothelial cells. There is usually formation of more or less concentric elastic lamellae, giving the appearance of *splitting or reduplication of fibers.*

The medial coat shows two types of change One consists of hypertrophy and is manifested by increase in the number or size of smooth muscle cells and increased thickness of the layer, and the other is represented by a relative increase in the amount of intercellular collagen throughout the media. The latter is not associated with fibrocytic proliferation, is more pronounced in the inner than in the outer half of the media, and in some instances results in atrophy rather than in hypertrophy of the smooth muscle cells.

In so-called *malignant hypertension*, acute necrotizing lesions are superimposed on the *chronic* arteriolar disease. This change is most common in the kidneys (Fig 12-2B), especially in the afferent arterioles of glomeruli, but

Fig 12-2. A Granular kidney (nephrc … with long-standing hypertension. The outer surface is uniformly nodular. Hematoxylin and eosin ×225.

products, and the result is impairment of muscle metabolism.

In instances of supervening cachexia, such as occur with disseminated carcinoma, chronic hypertension may not be associated with cardiac hypertrophy at the time of death In this circumstance, the heart has presumably undergone atrophy due to the cachexia, and this may be indicated by tortuosity of the coronary arteries.

Coronary arteriosclerosis tends to be more frequent and severe among patients with hypertensive heart disease than among nonhypertensive persons (Bell and Clawson). Apparently, hypertension favors the development of coronary sclerosis. About half the patients with acute coronary thrombosis and myocardial infarction have had previous hypertension. By its effect on cardiac nutrition, progressive coronary disease may limit compensatory reserve of the heart in hypertension and hence lead to myocardial failure. However, the relation of degree of cardiac enlargement to coronary disease is not entirely clear. Marked hypertrophy is observed both in hypertensive patients with significant narrowing or occlusion of the coronary vessels and in hypertensive patients with minimal coronary disease.

Along the same line, *no* clear interrelationship has been established between hypertension and arteriosclerosis of the large vessels For example, extreme arteriosclerosis of the aorta is observed in individuals who did not have elevated pressure, and conversely individuals with long-standing hypertension frequently show large-vessel disease not significantly more advanced than that observed in the corresponding age group without hypertension. However, *dissecting aneurysm of the aorta* is clearly related to hypertension from the pathogenetic standpoint.

No significant lesions of endocardium or pericardium occur in uncomplicated hypertensive vascular disease. Mural thrombi of ventricular or atrial endocardium are usually secondary to infarction from occlusive coronary disease. In cardiac arrhythmias, especially atrial fibrillation, or in decompensation, stasis thrombi occasionally develop in the auricular appendages and may serve as the source of emboli to brain, kidneys, spleen, and extremities.

When *cardiac insufficiency* supervenes, especially with repeated attacks of decompensation, the hypertrophy of the left ventricle is accompanied by dilatation and enlargement of the chambers, a corresponding decrease in the thickness of the wall, and flattening of the columnae carneae and papillary muscles. Also, the other chambers of the heart become hypertrophied and usually dilated. *Right ventricular hypertrophy* is a consequence of passive congestion of the lungs (due to long-lasting left heart failure). The enlargement of the chambers may be sufficiently marked to cause relative insufficiency of one or both AV orifices

Patients with *congestive heart failure* show passive hyperemia of the abdominal viscera. This varies in degree according to the duration and severity of failure For example, the *liver* may have prominent dark red central-zone markings, discrete or with lobular confluence, accumulation of fat giving the characteristic reddish-yellow *nutmeg liver,* or even cardiac cirrhosis Extravasation of fluid, usually of clear serous type, in the pleural and pericardial cavities, i.e , hydrothorax and ascites, and edema of the lower extremities, are also consequences of heart failure.

In hypertension, there are widespread lesions of the small arteries and arterioles These are most pronounced and frequent *in the kidneys* but are also found in the pancreas, gastrointestinal tract, adrenal gland, liver, brain, choroid, and skeletal muscles. Vascular changes occur in the spleen but are difficult to evaluate since spontaneous lesions in this organ are common in nonhypertensive individuals. The lesions in skeletal muscle are sometimes sufficiently well developed so that biopsy indicates the presence of vascular disease clinically (Foa et al).

Some investigators have regarded the vascular alterations associated with hypertension as similar to those occurring in arterioles on a physiologic basis with advancing age; i e., intimal hyalinization is the arteriolar counterpart of simple arteriosclerosis Such lesions are then believed to be hastened and accentuated by the vascular strain resulting from elevated blood pressure However, it cannot be stated with certainty from available evidence that hypertension actually plays a major role in the production of diffuse vascular disease In particular, it is difficult to explain on this basis

the marked predilection of the kidneys of hypertensive patients for the vascular lesions In contrast to the belief that hypertension causes the vascular disease, it has been suggested that *renal arteriolar disease is the primary lesion and serves to initiate the hypertension*

The vascular lesions of *chronic hypertension* have been described in detail by Moritz and Oldt. The most common change is intimal hyalinization, consisting of subendothelial deposit of homogeneous acidophilic material, which appears to represent an infiltration or expansion of the ground substance between the media and the endothelium This is commonly associated with either fatty or hydropic degeneration The hyalin is disposed as a circumscribed subendothelial plaque, or forms a subendothelial collar of uniform thickness, or can be annular and of irregular thickness It often involves the internal elastic membrane and may produce swelling, disruption, or obliteration of the lamellae. Marked hyaline change may result in considerable narrowing of the lumen of the vessel

Another frequent lesion is endothelial hyperplasia, especially in vessels over 50 μ in diameter. This change can also produce substantial reduction of the vessel lumen The hyperplastic endothelial cells tend to become spindle-shaped and resemble connective tissue cells Commonly, the proliferative change is associated with increase in elastic fibers between the newly formed endothelial cells. There is usually formation of more or less concentric elastic lamellae, giving the appearance of splitting or reduplication of fibers.

The medial coat shows two types of change. One consists of hypertrophy and is manifested by increase in the number or size of smooth muscle cells and increased thickness of the layer, and the other is represented by a relative increase in the amount of intercellular collagen throughout the media. The latter is not associated with fibrocytic proliferation, is more pronounced in the inner than in the outer half of the media, and in some instances results in atrophy rather than in hypertrophy of the smooth muscle cells.

In so-called *malignant hypertension*, acute necrotizing lesions are superimposed on the chronic arteriolar disease. This change is most common in the kidneys (Fig. 12-2B), especially in the afferent arterioles of glomeruli, but

Fig 12-2. A Granular kidney (nephr[illegible] [illegible] with long-standing hypertension. The outer surface is uniformly nodular. B. Kidney of patient with malignant hypertension and renal failure. Note vessels showing proliferative endarteritis, A; hyalinization of wall, B; and fibrinoid necrosis, C, also partly hyalinized glomerulus, D. Hematoxylin and eosin ×225.

may occur elsewhere, as in the gastrointestinal tract, adrenal glands, pancreas, liver, and brain. The necrosis consists of a smudgy, densely acidophilic accumulation of fibrinoid material, either homogeneous or granular, more or less obliterating the underlying structure, which shows partial or complete loss of nuclei. The fibrinoid substance frequently shows interspersed fatty vacuoles or extravasated red blood cells. Aneurysm, thrombosis, and hemorrhage may accompany the lesion As a rule an exudative component is either slight or absent

The necrotizing process is variable in extent. In the small arterioles, it tends to occupy the entire wall of the vessel, with substantial reduction of the lumen, but it may be patchy and involve only part of the wall Sometimes only the intimal layer shows the change and the lesion appears to be essentially subendothelial in location. However, the internal elastica is involved and reveals disruption, dispersion, or obliteration of fibers As is the case with the chronic arteriolar changes, the necrotizing process is commonly segmental in distribution along a given vessel.

In many instances of long-standing hypertension, the lesions of the kidneys constitute a striking feature of the pathologic picture (Fig 12-2A) This refers to the characteristic granular kidneys of hypertension, which comprise the picture designated as arteriolar nephrosclerosis. The organs are firm and slightly reduced in size, although occasionally they are substantially smaller than usual, and the capsule strips with increased difficulty. The outer surface is finely and uniformly granular, and small nodules of parenchyma, about 1 or 2 mm in size, project slightly above the reddish-gray network of retracted fibrous connective tissue. The organ cuts with increased resistance, and the cross section shows a narrowed cortex with indistinct striate pattern, medullary pyramids which are reduced in size, and thickening of the visible branches of the renal arteries.

The *nephrosclerosis*, which usually accompanies chronic hypertension, may vary from well developed to slight. On occasion, however, the kidneys of hypertensive patients appear grossly normal. While microscopically such organs as a rule show arteriolar sclerosis without parenchymal atrophy and fibrosis, there are instances where the kidneys show vascular disease which is apparently minimal and difficult to appraise as more significant than that present in nonhypertensive individuals. Observations of this kind have been cited as not supporting the concept of the renal origin of essential hypertension. A related item is the failure to find significant arteriolar sclerosis consistently in renal biopsies from patients in the early stage of hypertensive disease (Castleman and Smithwick).

The *renal lesion* consists essentially of an ischemic atrophy of parenchyma which is the result of arteriolar sclerosis Microscopically, there are glomerular lesions which range from thickening and wrinkling of the basement membrane to adhesions between tufts, hyalinization of tufts, and partial or complete conversion to fibrous whorls The tubules show secondary atrophy, and this is associated with interstitial fibrosis and lymphocytic exudate Nephrons with minimal involvement may reveal compensatory hypertrophy of tubules, but eventually these show degenerative change of granular, fatty, or hyaline-droplet type. The lesions of the small arteries and arterioles, as described above, are frequently pronounced. In malignant hypertension, the superimposed fibrinoid necrosis involves especially the vasa efferentia and may also involve the glomerular tufts As a consequence, there is extravasation of blood, and collections of erythrocytes within the tubules may be sufficiently extensive to produce grossly visible *petechiae*, best observed in the outer surface of the kidney after stripping the capsule Also the glomeruli frequently show proliferative lesions of the epithelium, adhesions between tufts and cellular exudate, producing a picture similar to that seen in acute glomerulonephritis. Especially marked in the malignant phase is endothelial proliferation of vessels, which is associated with elastic fiber reduplication and severe reduction of vessel lumens

In the *brain*, the most common pathologic lesion is *hemorrhage*, which often results in hemiplegia Hemorrhage is usually due to rupture of one or more of the small branches of the lenticulostriate arteries Since the latter arise at right angles from the middle cerebral artery, they may be subject to higher intravascular pressure than the usual dichotomous branches Moreover, the vessels are usually arteriosclerotic, and this may reduce their re-

sistance to internal pressure and lead to rupture Perhaps rupture of intramural miliary aneurysms of diseased arterioles may be a source of bleeding *It is believed by some that hemorrhage takes place from vessels situated in tissue previously devitalized by vasospasm, thrombosis, or embolism* (Globus). In malignant hypertension, there are often small foci of hemorrhage, necrosis, and edema associated with arteriolar necrosis.

The hemorrhage is usually well-defined and varies in size from a minute focus to a mass occupying most of the hemisphere. As the blood extravasates, it destroys nerve substance and compresses the surrounding structure *Cerebral edema* results, and the increase in intracranial pressure may cause death through herniation of the brain and compression of the brain stem. The hemorrhage may rupture into the subarachnoid space or into the ventricles. The blood clots rapidly, and the cross section is dark red and relatively dry The larger hemorrhages occur in the basal ganglia, thalamus, white matter of cerebral hemispheres, pons, and cerebellum

Microscopically, the region of recent hemorrhage shows infiltration of mononuclear cells and polymorphs. Scavenger cells appear and phagocytize the debris of tissue and myelin. The breakdown of blood furnishes both hemosiderin and hemotoidin, and these pigments are taken up by phagocytic cells Reactive gliosis and fibrosis are present, and the hemorrhage becomes cicatrized if small, or encysted if large The latter is typical of an area of remote encephalomalacia. The cyst is filled with thin fluid, usually brown or yellow in color, and the cyst wall is of similar but usually deeper color because of the presence of free pigment between cells and fibers. The cavity of the cyst may be traversed by a delicate weblike net of connective tissue fibers When recent or remote cerebral infarcts are observed in patients with hypertension, they usually are the result of thrombosis of sclerotic cerebral arteries or embolism from the heart. Recent infarction is usually *not associated* with significant gross hemorrhage. Healed *infarcts* are difficult to distinguish from foci of remote hemorrhage with cyst formation

4

Biochemical aspects of hypertension

HENRY A. SCHROEDER

All biologic phenomena can be eventually defined in terms of physics and chemistry. Although few such phenomena are comprehensible in these terms, a review of what is known of the abnormal biochemical changes in arterial hypertension may be rewarding, for intelligent therapy is directed towards reversing these changes.

The changes resulting in chronic generalized vasospasm leading to increased blood pressure are obviously of cellular origin and are probably a manifestation of altered cellular metabolism. The tissues involved are the vasomotor nerves, adrenal glands, kidneys, and smooth muscles of arterial and arteriolar walls After each area has been examined separately, their interactions may then be considered

ARTERIAL MUSCLE

There is no doubt that the smooth muscle fibers of the arterioles and small arteries are constricted in hypertension; the evidence for this assumption is indirect but overwhelming There is some evidence that smooth muscle of all arteries is constricted (Schroeder, 1953) The degree of constriction which causes profound increases in peripheral resistance may be very small, for *resistance varies as the fourth power of the radius of the vessel's lumen*. Indirectly, it is known or surmised that vessels to all organs and tissues are constricted approximately equally throughout the body, with one exception: arteries and arterioles of the kidneys are somewhat *more* constricted than the others (Goldring and Chasis, 1944).

Three mechanisms have been proposed to account for this fairly uniform vasospasm: (1) the sympathetic vasoconstrictor nerves are hyperactive; (2) there is a vasoconstrictor substance in blood which acts directly on smooth muscle, (3) smooth muscle becomes "sensitized" to normally acting sympathetic nerves or constrictor substances. As will be discussed, any two or all of these mechanisms can be active in human cases

The *reactivity of muscle*, probably including smooth muscle, can be affected by *alterations in ionic relationships*. Calcium, magnesium, sodium, potassium, hydrogen, and hydroxide ion concentrations affect muscular irritability according to the following schematic ratio in extracellular fluid

$$\frac{[Na^+ + K^+ + OH^-]}{[Ca^{++} + Mg^{++} + H^+]}$$

An increased concentration in the numerator increases irritability, an increase in the denominator decreases it This ratio appears to hold for vascular smooth muscle, in so far as is known *Thus, sodium, potassium, and alkalosis enhance vascular reactivity when increased in extracellular fluids, while magnesium, calcium, and acidosis decrease reactivity* (Sollmann, 1948) The situation is not so simple as this, however, for what is *inside* the cell membrane is obviously the determining factor, and this factor is governed by the permeability of the cell membrane to specific ions and its ability to transfer or reject ions (the "pump") Therefore, cellular reactivity probably depends upon a potential governed in part by the gradient between what is inside and what is outside in terms of a specific ion

Cellular permeability is affected presumably by both hydrogen ion concentration and total osmolarity, furthermore, displacement of *one ion* by another (sodium for potassium, for example) appears to occur within the cell under certain clinical conditions. Therefore, the interrelationships of the bulk cations in affecting muscular irritability can be complex when considered in the whole body.

A further restriction of this ratio to the *potassium gradient* alone has been found in work on *nerve*, skeletal muscle, and smooth muscle (Bohr, Brodie, and Cheu, 1958) When K_I is the intracellular and K_E the extracellular concentration, and C is a constant, then

$$\text{Log}\,\frac{K_I}{K_E}\times C = \text{resting potential}$$
$$= \textit{threshold for response}$$
$$= \frac{1}{\textit{responsiveness}}$$

By this formula, sodium, magnesium, calcium, and hydrogen ion concentrations are not involved. They do, however, exert effects singly on reactivity and must be taken into consideration in any uniform theory, even if their effects on the gradient of intracellular-extracellular potassium turn out to be indirect.

Although permeability of cells to cations is altered by overhydration, dehydration, acidosis, or alkalosis, for purposes of this discussion consideration will be confined to *permeability to* sodium, potassium, and magnesium This function appears to be under partial control of some adrenal cortical hormones. *Desoxycorticosterone acetate* and *aldosterone* have the property of causing cells to gain sodium and lose potassium and possibly magnesium (Hajdu, 1953)

One interesting and fundamental observation has demonstrated that vascular smooth muscle of hypertensive rats and patients actually contains more sodium than normal muscle, and is therefore possibly edematous In rats, hypertension caused by either *renal* ischemia or the administration of *desoxycorticosterone* was accompanied by aortic smooth muscle containing more *sodium* and potassium and *less* magnesium than that of *control animals* (Tobian and Binion, 1954). The *renal* arteries of hypertensive patients showed more sodium and water, with *normal* potassium and magnesium concentrations (Tobian and Binion, 1952). This finding has led to the postulate that *swelling of the wall* (rather than *active vasoconstriction*) *accounts* for the increased resistance in the peripheral vascular bed leading to hypertension It does not rule out, however, the probability that such vessels are hyperreactive

In hypertensive patients, examination of the blood which bathes vascular smooth muscle shows the following: slightly *increased sodium* concentration (with considerable overlap), slightly decreased *magnesium concentration (with considerable* overlap), normal potassium concentration (Albert et al., 1958). It is possible that these tendencies, in themselves not diagnostic, are a reflection of a slight overproduction of mineralocorticoids by the adrenal cortex, for excessive production causes changes in the same directions.

ADRENAL CORTEX

Among the several steroids secreted by the adrenal cortex, one is primarily concerned with electrolyte balance and thus, indirectly, with vascular reactivity: *aldosterone*. Although many attempts have been made to *implicate* the adrenal cortex in hypertension, *there is no* clear-cut evidence that this organ initiates or *maintains* hypertension save in one condition: *when* the cortex itself is hyperplastic or contains an adenoma which secretes aldosterone. Then, *and only then*, is there proof of cause and *effect*, for removal of the adenoma usually causes regression of the disease (Conn, 1955)

In spite of the lack of evidence, *bilateral adrenalectomies* have been performed *for* hypertension with variable results. *In* the *absence of the* adrenal glands, the body finds *it difficult* or impossible to maintain vascular *tone and* reactivity; untreated Addison's disease *and* severe hypertension cannot exist together Therefore, the fact that blood *pressure may* fall after adrenalectomy *is in* no way indicative of prior hyperactivity *of* the gland, for normal blood pressure likewise will fall after adrenalectomy

Patients with certain *types* of *cortical adenomas* excrete excessive amounts of aldosterone in their *urine* and show sodium retention, urinary *loss of* potassium, and hypertension (Conn, 1955). *These* findings usually revert to *normal* when the adenoma is removed, although the *hypertension* may not *entirely*

regress. However, most hypertensive patients excrete a slight excess of urinary aldosterone (Genest et al., 1956), and some show the plasma electrolyte changes enumerated above. Therefore, the effects of steroids on electrolytes and on vascular reactivity should be examined in order to ascertain what possible primary or secondary etiological actions they might have.

Adrenal Cortical and Electrolyte Influences on Vascular Reactivity. There is no doubt that salt and steroids can affect general vascular reactivity (Goldman and Schroeder, 1948). *Desoxycorticosterone* (*DOC*) has been the most widely studied; it and sodium chloride produce experimental (rat) hypertension (Braun-Menéndez, 1951) and a syndrome similar to toxemia of pregnancy (Masson et al., 1953). Although DOC alone will not cause hypertension in rats, salt alone in large amounts will (Sapirstein et al, 1950). In man, the vascular response to graded doses of epinephrine and norepinephrine is enhanced by DOC and depressed by severe restriction of dietary salt (Raab et al, 1952), although these findings were not wholly confirmed by Dahl (1957) Hypertension has sometimes accompanied the chronic administration of adrenocorticotropic hormone (ACTH), cortisone, and hydrocortisone, and patients with Addison's disease frequently become hypertensive when treated with salt and DOC (Perera et al, 1944)

The mechanism of this increased irritability has not been exactly elucidated Probably it involves intracellular alterations in the four cations concerned in smooth muscular reactivity; one could make a reasonable assumption that the potassium-sodium ratio in the cell was lowered or the magnesium-calcium ratio was changed, or both. This basic point deserves careful study of the four ions and the effects of steroid hormones upon their intracellular-extracellular balances.

When these various findings are considered together, it appears that salt and adrenal cortical steroids somehow cause a change in arterial smooth muscle. This change has been characterized by hyperirritability to the injection of the vasoactive agents epinephrine and norepinephrine Depletion of salt reduces irritability. Therefore, *a present concept of some forms of hypertension involves alteration in sodium, potassium, and possibly magnesium ratios within the smooth muscle cell, making it more sensitive to normally acting vasospastic influences* This alteration results from remote influences involving intake, excretion, and steroids.

Therapeutic Implications. Measures aimed at depletion of body sodium in the hope that this cellular alteration may be reversed involve severe restriction of dietary salt (Kempner, 1948), promotion of urinary excretion of sodium by electrolyte diuretics (Taggart, 1958), and (experimentally) the use of antiadrenal compounds (Stafford et al, 1953, Schroeder, 1953; Sturtevant, 1957). All these measures are moderately effective in some patients. That this cellular electrolytic alteration is not the *sole* cause of *all* hypertension (although it may be the primary cause in a small percentage) is suggested by the failure of these methods completely to reverse the vasospastic state in all patients

State of Kidneys with Respect to Salt. Hypertensive kidneys excrete more salt in response to a salt load (intravenous hypertonic saline solution) than do normal kidneys (Farnsworth and Barker, 1946; Green et al, 1952) This abnormal response is the one renal metabolic defect which seems to be consistent They also excrete more sodium and chloride during a resting period, provided the hypertension is not severe Even patients with mild hypertension and normal renal plasma flow excrete more urinary sodium, potassium, and chloride than do normotensive subjects (Cottier et al, 1958) Therefore, *the hypertensive kidney is a salt-losing kidney.* Obviously such chronic salt loss would be difficult to measure and would in time result in a state of severe hyponatremia unless the lost salt were replaced by diet and attempts made by the body to conserve it

Because of this defect, it may justly be theorized that regulatory forces probably come into play in order to maintain body sodium These involve increased formation of aldosterone in order to conserve urinary salt, and increased salt intake perhaps a result of salt hunger However, the actual losses needed to call out conserving mechanisms, when considered in the long term, may be small, for there is only a bit more than 120 Gm exchangeable salt in the adult body, and only about 20 Gm in the blood

Therefore, in hypertension, there are found the following alterations with respect to electrolytes and their hormonal governors salt-losing kidneys, slightly increased excretion and presumably formation of aldosterone, possible ingestion of more than normal amounts of salt, and hyperirritability of vascular smooth muscle, probably resulting from sodium and potassium imbalances within the cells as a result of excess aldosterone production One may well ask which comes first? The answer is not known, but the clinical indications are that *in some, probably few, cases the process is initiated by excessive production of aldosterone from an adenoma, while in most cases the renal defect initiates the adrenal mechanism as a compensatory phenomenon*

THE RENAL BIOCHEMICAL ABNORMALITY

Little is known of the exact biochemical abnormality in the kidneys of hypertensive persons Until the hypertensive process has damaged the kidney by causing renal vascular disease, the urine may appear normal, renal function may be normal by all the usual gross tests, and no abnormality of blood suggestive of renal disease may be found There are, however, several hidden alterations which can be detected by special procedures. There is usually a little more urinary sodium chloride and water than in normal persons, the pH tends to be a bit more acid, and the ratio of ammonia to titratable acid is reduced (Perry and Schroeder) The renal plasma flow is reduced in all cases but the mildest, when it may be normal at rest, glomerular filtration rate is usually increased in relation to total plasma flow, and the calculated result suggests constriction of the efferent arterioles (Goldring and Chasis, 1944) Oxygen consumption by the kidney is usually found, by calculation, to be reduced (Schroeder, 1953, Huckabee, 1958) Primary amines in blood are elevated (Stock and Schroeder, 1950; Olsen and Schroeder, 1950a)

A little more is known of the changes in experimental hypertension Oxygen tension of the renal cortex is reduced (Olsen and Schroeder, 1950b) Oxygen consumption by the kidney may be reduced (Olsen, 1951) The cortex is acid (Olsen and Schroeder, 1950b) When kidneys are removed, they show enzymatic changes: reduced amino acid oxidation, reduced deamination of amines by monamine oxidase, reduced transamination (Olsen, 1951), reduced dehydrogenation of succinate and oxidation of cytochrome (Raska, 1943) Thus, there is a general depression of oxidative enzymes, which may be specific or may be the result of destruction of renal tissue by the procedure. Naturally, one wonders how these alterations can raise blood pressure, if they do The exact pathways are unclear, although there are a number of attractive hypotheses to explain them.

To account for the increase in primary amines (most of which are vasoactive) there is the theory of Holtz (1939), which deals with two types of enzymes, certain amino acid decarboxylases and monamine oxidase.

Decarboxylases are known for tyrosine, dihydroxyphenylalanine (DOPA), tryptophan, 5-hydroxytryptophan, leucine, and histidine. These amino acids, when they lose their carboxyl groups, form the vasoactive amines tyramine, dihydroxyphenylethylamine, tryptamine, serotonin, isoamylamine, and histamine, which are then deaminated to their unstable aldehyde degradation products by monamine oxidase and, in the special case of histamine, by histaminase or diamine oxidase Deamination by monamine oxidase requires oxygen, and the enzyme is especially sensitive to oxygen lack, its activity being in direct relationship to oxygen tension (Kohn, 1937) Decarboxylases are anaerobic, requiring no oxygen for activity

It is probable that some urinary ammonia comes from amino acids other than glutamine, which has been shown to contribute about two-thirds of the total ammonia excreted There is a divergence of opinion on this matter, but several amino acids are capable of contributing ammonia (Meister, 1956), partly through the pathway described. One can then logically predict some of the fundamental changes which would take place if renal oxygen tension were reduced enough partially to inhibit renal monamine oxidase. Decarboxylation would proceed anaerobically as usual Primary amines resulting therefrom would escape deamination by the kidney and would enter the general circulation Those that escaped deamination in the lungs (where there is considerable monamine oxidase) would act on blood vessels in the periphery, including the kidney, deamination would be shifted from

kidney to pulmonary and systemic blood vessels and liver. In the urine there would be less ammonia and a little more sodium, with a tendency for the urine to be on the acid side. The cortex of the kidney would be acid. Primary amines would be found in arterial blood in increased amounts. In other words, *reduction in renal oxygen tension would cause all the minor abnormalities which are actually found* (Schroeder, 1957).

Would these metabolic changes raise blood pressure? Probably not. Aside from the amine of DOPA, the others are relatively weak pressor substances, and relatively large amounts would be necessary to cause chronic hypertension unless monamine oxidase were also depleted from the body (Schroeder and Olsen, 1950b). They would also have been detected in large amounts before this time. One can accept the fact that renal oxygen consumption and oxygen tension are reduced in most cases of hypertension, but this alone cannot be implicated as a cause. One must look for more powerful pressor substances

Two converging lines of investigation, conducted for the past 20 years, proved to be rewarding. One has involved the isolation of a pressor substance from arterial blood of hypertensive patients (Schroeder and Stock, 1942). This substance, probably a polypeptide, constricts vascular smooth muscle which has been blocked by sympatholytic agents, i e., it is a direct muscle stimulant (Schroeder et al, 1955). It has been named *pherentasin* (Schroeder and Olsen, 1950). It can be obtained from extracts of arterial blood of moderately severe and severe cases of hypertension, but little or none is found in mild cases Restoration of normotension by chemotherapy results in its disappearance.

The other has involved *angiotensin*, a polypeptide resulting from the enzymatic action of renin on an alpha 2 globulin in blood (Braun-Menéndez et al., 1940, Page and Helmer, 1940).[1]

Renin is a proteolytic enzyme in kidney which is released into the renal venous blood under conditions of acute reduction of renal blood flow. Upon release, it reacts with its substrate, providing a decapeptide, *angiotensin I* (Skeggs et al, 1954). A peptidase in blood, called the converting enzyme, removes two of the amino acids, resulting in the very active vasoconstrictor octapeptide, *angiotensin II* (Lentz et al., 1956). Both these peptides have been synthesized (Bumpus, Schwarz, and Page, 1957). A substance with the activity of angiotensin has been obtained from hypertensive blood by alcoholic precipitation (Skeggs et al, 1952).[2]

Unfortunately for the renin hypothesis, no renin has been found in renal venous blood in chronic hypertension (Taquini and Fasciolo, 1949, Braun-Menéndez et al., 1946; Quimby et al., 1945) Although repeatedly searched for, renin release ceases after a few days or weeks of chronic renal ischemia Therefore, *it is generally agreed that while renin may be the effector substance for acute vasospastic states such as congestive heart failure, acute nephritis, toxemia of pregnancy, etc.* (Dexter and Haynes, 1944), *it can scarcely be involved in chronic vasospastic states because it is not found in them.* The discrepancy between finding an angiotensin-like substance presumed to be the product of the reaction of renin, and not finding renin, has not been resolved.

Be that as it may, extracts of human hypertensive blood do contain a vasoactive substance of peptide nature, whether this substance is called pherentasin or angiotensin and whether it comes from the kidney or elsewhere The two substances, pherentasin obtained from human blood and angiotensin obtained from animal kidney and animal globulin, are remarkably similar in most, but not all, of their reactions (Schroeder, 1957). If pherentasin is actually human angiotensin, the differences may be ascribed to different amino acids in the species-specific globulin (Braun-Menéndez and Paladini, 1958). Again this point has not been resolved

At any rate, it is fairly safe to assume that part of the chronic vasospasm found in hypertensive states is caused by a peptide in blood, released probably by proteolysis, but with its

[illegible] to the material
by [illegible]
by [illegible]
term [illegible]
Buntz, 1958).

[2] It is probable that the material procured from blood is the same substance called pherentasin in this discussion, for methods of extraction and concentration are similar. It has not been chemically identified as angiotensin

actual source unknown. *All the indirect evidence, however, points to the kidney as the source.*

The nature of this peptide is not known. By analogy with angiotensin, which it resembles in its direct vascular action and in reactions designed to inactivate it, this peptide probably contains eight amino acids, of which aspartic acid and arginine are at one end and phenylalanine at the other (Elliott and Peart, 1956; Skeggs et al, 1956, Rittel et al, 1957) There is a distinct possibility, however, that many hypertensins may result from proteolysis Until the substance in blood is purified and its amino acid content is characterized exactly, one can learn little more about it and from whence it comes.

NERVES

An increase in the "tone" or reactivity of sympathetic vasoconstrictor nerves could easily result in intermittent hypertension and its characteristic renal hemodynamic profile Opinions and experiments differ on whether or not sympathetic nerves discharge more easily, i e, have a hair trigger response, in hypertension than in normotension Data convincing enough must be indirect, experiment is now most difficult, if not impossible, in human subjects *In the experimental animal, but not in the human being, there is indirect evidence that in the later stages of renal hypertension, the sympathetic nerves are more active and play an increasingly important role in the chronic vasospasm, while in the early stages the role of the kidneys is predominant* (Ogden, 1947)

In human beings, the indirect evidence for increased sympathetic nervous activity is as follows The blood pressure may be labile and widely variable, especially in cases with no demonstrable renal involvement (Schroeder, 1957). Traube-Hering and respiratory variations are often marked (Janeway, 1904; Schroeder and Menhard, 1956) The pressor or vasospastic effects of central vasomotor stimuli, from inhalation of carbon dioxide [illegible]

[illegible] of hypertensive patients have increased catechol amines in the urine (von Euler et al, 1954), and none have increased amounts in blood (Raab, 1953) Many patients, also, do not show the exaggerated responses to central vasomotor stimuli, suggesting that they differ in some fundamental manner from those who do.

Perhaps the best way of assessing the relative part that nerves can play in the total vasospastic picture is by cutting them or blocking them. *When surgery or chemical ganglionic blockade is performed on a group of patients, the responses vary from almost none to almost 100 per cent* (Doyle and Smirk, 1955). This variation in response is universal, by all direct or indirect methods used. Therefore, one is forced to the conclusion that there is no universal alteration in sympathetic tone, but that *a variable portion of the vasospasm is sympathetically induced in each patient*, and that the remainder of the vasospasm is the result of other mechanisms.

Nor is this variability apparently dependent upon the sensitivity of arterial muscle, although that is hard to demonstrate. *It is true that* reducing muscular hyperactivity by salt restriction or sodium diuretics enhances the effects of nerve-acting drugs. But only remotely could the two actions, sympathetic hyperactivity and muscular irritability, be connected biochemically.

It is known that certain cations are necessary for nerve transmission Sodium within the nerve, according to one authority (Lorente de Nó, 1949), is necessary for the formation of quaternary ammonium compounds which revert to tertiary nitrogen with the discharge of energy for nerve transmission. The nerve deprived of sodium is hypoactive Nerves without their sheaths (autonomic nerves) are more *susceptible* to sodium deprivation than are myelinated nerves. Therefore, by analogy with in vitro experiments, even a slight depletion of body sodium might reduce sympathetic nerve activity, just as it would reduce smooth muscular reactivity Others believe that potassium is necessary for nerve transmission and that reactivity depends upon the ratio of potassium inside and outside the nerve, just as cardiac muscle is affected by this ratio (Jenerick and Gerard, 1953) Discharge of the nerve, like contraction of muscle, is accompanied by loss of potassium

Whatever the final conclusion, one may conjecture with reasonable accuracy that sodium, potassium, and possibly magnesium may be concerned with nerve transmission, that un-

myelinated nerves are more susceptible to changes in extracellular cations than are myelinated nerves, and that nerve activity may be altered by alterations in ratios of cations outside and inside the nerve fiber If that is so, the adrenal cortical steroids may act as regulators of these cations, both in the whole body and within cells.

There is another method by which sympathetic nerves can become overactive in hypertension, and that is by direct stimulation of the brain For a long time it was believed that hypertension was a "psychosomatic disease," for the personalities of hypertensive patients differed from those of normal persons, and it was convenient to think that the pace of modern living imposed stresses upon persons so constituted as to "bottle up" their psychic complexes and express them through discharges of their sympathetic nerves. Not until the advent of therapy did it slowly become evident that *emotional tension, so prevalent in hypertensive persons, was relieved by any surgical or chemical method which caused sustained normotension.* No study of personality has been made to determine whether or not therapeutic normotension is associated with a change in the subnormal assertiveness and obsessive-compulsive tendencies, said to be part of the "hypertensive personality" (Binger et al., 1945), but the tension and anxiety presumably resulting therefrom are relieved.

If the emotional tension which presumably causes sympathetic discharges is not the result of external stimuli, could it be the result of metabolic changes in the brain? It definitely could, although such changes are inferential and the causative pathways theoretical There are increased amounts of primary amines in hypertensive blood These amines, while having vascular effects, may also have direct stimulatory or depressant activity on local areas of brain The cerebral action of *serotonin*, a primary amine, has been well studied, apparently it is an effector substance for the posterior hypothalamic pathways from cortex *Epinephrine* and *norepinephrine* are also very likely mediators of certain areas of cerebral activity, and both *tyramine* and *isoamyl amine* are cerebroactive. In fact, the brain contains a considerable amount of monamine oxidase, which deaminates these amines Advantage is taken of both amphetamine and iproniazid as cerebral stimulants; both have the property of inhibiting the activity of monamine oxidase, thus preventing destruction of primary amines and allowing them to act. In any organ where deamination is suppressed by diminished oxygen tension but anaerobic decarboxylation can continue, primary amines can be expected to affect cerebral metabolism *This mechanism, which is actually "somatopsychic," may account for the anxiety and nervous tension so prevalent in hypertensive states.*

One other hypothesis states that the inherited characteristics of the individual are such that he has increased emotional tension. Such hereditary tendencies are not explicable in biochemical terms, although it is known that hereditary or congenital absence of a single enzyme system will cause a specific metabolic disease There is no evidence that hypertensive persons have less monamine oxidase than normotensive ones, nor is such a state of affairs likely on a congenital basis. Personality traits may be inherited, however, and so may the ability to react to stress by vasospasm, one fundamental characteristic of most hypertensive individuals (Schroeder, 1957). But nothing is known about the metabolic changes, or more likely, the anatomic ones, which could result in this common characteristic of man

CHEMICAL METHODS AFFECTING THE METABOLIC ALTERATIONS

Because pharmacology is a branch of biochemistry, and because a few chemical tools are now available which will alter the abnormal cellular metabolism in hypertension to cause the appearance of normality, a discussion of logical therapy is in order Understanding of the basic actions of these chemical agents is at best imperfect, but the principal effects have been well described Although no drug acts on one function without affecting others, and no function so affected fails to react on others, the antihypertensive drugs have, in the main, primary actions which either tend to restore normality or to cause further abnormality which superficially appears more normal.

Agents Acting on Autonomic Nerves. Although not a chemical, probably the best tool

for removing the influence of the sympathetic nerves is the surgeon's knife. It is not always the most effective because nerve trunks vary widely in their origins from various ganglia, sensitization to humoral sympathetic effector substances occurs within a few days after the resection unless only preganglionic nerves are severed, and the ability of sympathetic trunks to regenerate is remarkable The more extensive the sympathectomy, the higher is the percentage of favorable results In all types, the innervation of the kidneys is severed. Extent has included anterior root section affecting 4 to 8 dorsal ganglia (Page and Heuer, 1937), supradiaphragmatic sympathectomy affecting 5 to 7 (Peet, 1935), lumbodorsal affecting 8 to 11 (Smithwick, 1940), and subtotal affecting 15 or more (Grimson, 1941) At best, the percentage of "cures" of the disease amounts to about one-third, attesting to the dual pathogenetic pathways present in most cases

Against this background, "reversible chemical sympathectomy at the ganglionic synapse" has been achieved with *ganglionic blocking agents*

These drugs are believed to compete with acetylcholine, preventing synaptic transmission of nerve impulses, and thus may be considered as antimetabolites Most of them are quaternary ammonium compounds (as is acetylcholine), one (mecamylamine and its derivatives) contains tertiary nitrogen Unfortunately, they also block acetylcholine transmission of parasympathetic impulses

The percentage of good control of hypertension (strict normotension) achieved by this form of sympathectomy is about equal to that following extensive surgical measures, again attesting to the duality of pathogenetic influences

No strictly adrenolytic or sympatholytic agent is now available which affects hypertension favorably without intolerable side effects Thus, there is no antimetabolite for norepinephrine useful in hypertension

Stimulation of the carotid sinus and aortic depressor nerves by *veratrum* and its derivatives causes intermittent depression of blood pressure The nature of the chemical reaction involved is not known.

Cerebral sympathetic centers are depressed by *reserpine* and its analogues, chemical cousins to yohimbine

Something is understood of the mode of action of reserpine Tracts from the cerebral cortex to the posterior hypothalamus (the central sympathetic center) are blocked in some manner by which certain primary amines, notably serotonin (5-hydroxytryptamine), epinephrine, and norepinephrine are removed from brain substance (Brodie et al., 1957). Serotonin is also removed from platelets and intestinal wall (Shore et al., 1956). Although the drug does not remain in the tissues, blockade lasts for hours or days. The total effect of tolerable amounts of this form of blockade on the somatic portion of the sympathetic system is relatively minor.

Agents Acting on Adrenal Cortex. Experimental antimetabolites to desoxycorticosterone (DOC) are known An antialdosterone would be a most valuable agent One anti-DOC, which prevents DOC and salt hypertension in rats (Stafford et al., 1953), has been used in a few selected human beings with favorable results on blood pressure, in fact, in one instance following a series of injections, intravenous norepinephrine was required for several days to maintain normal blood pressure in a severely hypertensive woman. The material is irritating to the tissue when injected and has been abandoned Another anti-DOC has recently been used to lower blood pressure in rats with three types of experimental hypertension (Sturtevant, 1957) Further work along this line will be rewarding.

Depletion of body sodium does not depress the adrenal cortex All the evidence is to the contrary, i.e., depletion stimulates the cortex and promotes hypertrophy of the zona glomerulosa (Deane et al., 1948), where aldosterone is believed to be formed

Agents Acting on Sensitivity of Vascular Muscle. There are two types, the first affecting smooth muscular sensitivity indirectly by causing bodily depletion of sodium or other electrolytes, and the second having a more direct action, on muscle itself, on circulating vasoconstrictor substances, or on both

Depletion of body sodium by lowering the intake to very small amounts lessens the reactivity of the blood vessels to epinephrine and norepinephrine even when DOC is given (Raab, 1953) By analogy, this action could be considered to occur even if the amount of

myelinated nerves are more susceptible to changes in extracellular cations than are myelinated nerves, and that nerve activity may be altered by alterations in ratios of cations outside and inside the nerve fiber If that is so, the adrenal cortical steroids may act as regulators of these cations, both in the whole body and within cells.

There is another method by which sympathetic nerves can become overactive in hypertension, and that is by direct stimulation of the brain. For a long time it was believed that hypertension was a "psychosomatic disease," for the personalities of hypertensive patients differed from those of normal persons, and it was convenient to think that the pace of modern living imposed stresses upon persons so constituted as to "bottle up" their psychic complexes and express them through discharges of their sympathetic nerves. Not until the advent of therapy did it slowly become evident that *emotional tension, so prevalent in hypertensive persons, was relieved by any surgical or chemical method which caused sustained normotension.* No study of personality has been made to determine whether or not therapeutic normotension is associated with a change in the subnormal assertiveness and obsessive-compulsive tendencies, said to be part of the "hypertensive personality" (Binger et al, 1945), but the tension and anxiety presumably resulting therefrom are relieved.

If the emotional tension which presumably causes sympathetic discharges is not the result of external stimuli, could it be the result of metabolic changes in the brain? It definitely could, although such changes are inferential and the causative pathways theoretical There are increased amounts of primary amines in hypertensive blood. These amines, while having vascular effects, may also have direct stimulatory or depressant activity on local areas of brain. The cerebral action of *serotonin*, a primary amine, has been well studied, apparently it is an effector substance for the posterior hypothalamic pathways from cortex *Epinephrine* and *norepinephrine* are also very likely mediators of certain areas of cerebral activity, and both *tyramine* and *isoamyl amine* are cerebroactive. In fact, the brain contains a considerable amount of monamine oxidase, which deaminates these amines Advantage is taken of both amphetamine and iproniazid as cerebral stimulants; both have the property of inhibiting the activity of monamine oxidase, thus preventing destruction of primary amines and allowing them to act. In any organ where deamination is suppressed by diminished oxygen tension but anaerobic decarboxylation can continue, primary amines can be expected to affect cerebral metabolism. *This mechanism, which is actually "somatopsychic," may account for the anxiety and nervous tension so prevalent in hypertensive states.*

One other hypothesis states that the inherited characteristics of the individual are such that he has increased emotional tension Such hereditary tendencies are not explicable in biochemical terms, although it is known that hereditary or congenital absence of a single enzyme system will cause a specific metabolic disease. There is no evidence that hypertensive persons have less monamine oxidase than normotensive ones, nor is such a state of affairs likely on a congenital basis Personality traits may be inherited, however, and so may the ability to react to stress by vasospasm, one fundamental characteristic of most hypertensive individuals (Schroeder, 1957). But nothing is known about the metabolic changes, or more likely, the anatomic ones, which could result in this common characteristic of man.

CHEMICAL METHODS AFFECTING THE METABOLIC ALTERATIONS

Because pharmacology is a branch of biochemistry, and because a few chemical tools are now available which will alter the abnormal cellular metabolism in hypertension to cause the appearance of normality, a discussion of logical therapy is in order Understanding of the basic actions of these chemical agents is at best imperfect, but the principal effects have been well described. Although no drug acts on one function without affecting others, and no function so affected fails to react on others, the antihypertensive drugs have, in the main, primary actions which either tend to restore normality or to cause further abnormality which superficially appears more normal

Agents Acting on Autonomic Nerves. Although not a chemical, probably the best tool

bee, 1958). In some manner not understood, this alteration sets in motion the *renal pressor mechanism*, with release of peptide pressor material into the blood stream. The result is further vasoconstriction, now on a humoral pressor mechanism acting directly on vascular smooth muscle. The vasoconstriction, which would be intermittent were it mediated solely through nerves, becomes steady and continuous. If it began through the mediation of renal vascular lesions, it would be expected to be continuous from the onset. In these terms, then, a major vicious circle is initiated by reduction of renal blood flow or renal hypoxia from either nervous or anatomic causes.

Normal vascular smooth muscle becomes sensitized both to nervous impulses and presumably to peptide constrictors by alterations in the gradient of simple bulk cations These alterations are initiated by overproduction of mineralocorticoids Overproduction may be great, as a result of an active adrenal cortical adenoma (primary aldosteronism), or, more commonly, slight, as a result of a physiologic response to renal loss of sodium The loss of sodium is most likely a local metabolic defect resulting from hypoxia and the slight change of renal tissue from aerobic to anaerobic metabolism Thus, a minor "vicious circle" is established, initiated by renal loss of salt and resulting in increased vascular sensitivity.

This change of renal metabolism allows some primary amines to enter the general circulation. There, they probably have some vascular effects, but mainly they *alter the metabolism of brain* The result may be tension, anxiety, and increased cerebral activity leading to greater outflow from the hypothalamus down the sympathetic nerves In this manner, a theoretical minor vicious circle is established by diminution of renal deamination from hypoxia, causing increased nervous activity and its resultant somatic discharges.

The manner by which these vicious circles may be started, eventually causing disease, is unknown. Depending upon one's own viewpoint, one may enter them at several points. Via the brain, hypertension becomes a psychosomatic disease, a result of the *Sturm und Drang* of modern life, or a functional brain disorder. Via the adrenal glands, it becomes a result of an unexplained hypercorticism. Via the kidneys, it is the manifestation of renal vascular disease, developing in the small vessels in some unknown manner, or in the large, from atherosclerosis.

As we have intimated, human cases of hypertension can be found which illustrate all these initiating causes But the majority of cases, lumped together as "essential" hypertension, do not clearly show any of these causes

In strictly biochemical terms, the renal accumulation and storage with age of a *substance which would produce the enzymatic* alterations of hypoxia would initiate these vicious circles quite ideally. Likewise, *progressive deficiency* of a substance, either actual or *conditioned*, which normally acts to *metabolize primary amines and peptide vasoconstrictors would likewise* initiate these vicious circles Certain trace metals have been believed to be directly concerned. Hypertension *can be produced* by several methods and treated successfully by several drugs and procedures While hypertension should be considered *the result* of enzymatic imbalances in one or more specific organs (the kidney being the most likely), its exact biochemical pathogenesis still remains obscure.

aldosterone produced were increased by sodium depletion.

Depletion of body sodium by diuretics should be expected to accomplish the same result. Mercurial diuretics exhibit some such effect (Heider et al., 1958). Chlorothiazide, a new sodium diuretic, which also acts upon potassium, has the same effect as severe restriction of salt (Taggart, 1958). It probably inhibits renal carbonic anhydrase (Beyer, 1958).

Both these methods enhance the activity of agents acting on nerves, suggesting that their primary action is indirect (i.e., on sodium or other cations in smooth muscle). Neither causes reversal of the hypertensive process in more than a small percentage of cases, again suggesting the duality of pathogenic influences.

The second type of agent is characterized by *hydralazine*, a member of a group of antihypertensive chelating agents.

More is known about the biochemical activity of hydralazine than of that of any of the other drugs (Schroeder, 1957). It chelates iron, copper, vanadium, manganese, nickel, silver, mercury, and tin. It forms a complex with some carbonyl groups and with sulfhydryl. It binds certain proteins and polypeptides, including hypertensin. It reacts with certain enzymes in vitro, enhancing the activity of monamine oxidase quite markedly (which would theoretically increase the destruction of primary amines). It is an antienzyme for DOPA decarboxylase and histaminase.

It weakly blocks most simple vasoconstrictor primary amines in the intact animal but strongly inhibits the pressor actions of pherentasin and vasopressin. On the isolated strip of rabbit aorta it weakly inhibits primary amines but strongly abolishes constriction caused by hypertensin and pherentasin. In vascular beds of animals, it dilates constricted vessels, whatever the cause of the constriction, but does not further affect dilated vessels. In hypertensive man, it is the only known drug which dilates the vessels of the kidney.

When hydralazine is given to patients and blood pressure is lowered to normal, pherentasin, previously detected in blood, disappears (Schroeder et al., 1955). Hydralazine alone, however, seldom causes normotension unless an agent acting on nerves is used concomitantly.

Other drugs which destroy the activities of hypertensin and pherentasin in vitro and are antihypertensive in man are thiocyanate, nitroprusside, dimercaptopropanol (British antilewisite), ethylenediaminetetraacetate (EDTA), and azide, all agents capable of chelating or binding trace metals. Because of this common property, not shared by the drugs acting on nerves, it is believed without definitive proof that hypertensin and pherentasin contain a trace metal chelated to the polypeptide, and that trace metals are concerned in hypertension. Actually, hypertensive urine contains many times the normal amount of cadmium.

Because of dual or triple pathogenetic influences acting in most cases of human hypertension, dual or even triple therapeutic tools must be used in order to achieve complete reversal of the process. Clinical results bear this out (Schroeder et al., 1954).

INTERACTION OF THE BIOCHEMICAL ABNORMALITIES

It is not the purpose of this discussion to set up a theoretical although logical system of the pathogenesis of human hypertension. Definition of the pathways by which these local metabolic alterations can interact, however, provides a framework upon which any theory can be based, and further illustrates essential "vicious circles" which appear to operate and which can now be broken by appropriate therapy.

Sympathetic nerves act to constrict arterial smooth muscle through their chemical mediator, *norepinephrine*. Therefore, excessive nervous activity or excessive amounts of norepinephrine (as in certain pheochromocytomas) will constrict the vascular bed generally.

The *kidneys* take part in the general vasoconstriction to a greater extent than do other vascular beds (Smith, 1943), causing reduction in renal plasma flow and, presumably, some degree of hypoxia. *Vascular lesions* (pyelonephritis, glomerulonephritis, atherosclerosis, etc.) can also produce reduction of renal plasma flow and some degree of hypoxia—unless the effective blood pressure rises enough to counteract the lessened flow. Since the kidney has one of the highest oxygen consumption rates of any organ, presumably reduction of blood flow will cause partial conversion from aerobic to anaerobic metabolism (Hucka-

pathologic process in some organ, it follows that the resultant hypertension usually is *secondary* to whatever determines the increased peripheral vascular resistance Instead of dividing hypertension into primary and secondary types, therefore, it might be better to speak of *specific* and *nonspecific* types, the former consisting of those cases in which the etiology is considered to be known This would apply particularly to the hypertension associated with an abnormality of an endocrine organ (a pheochromocytoma of an adrenal gland, for example) or with renal disease, such as glomerulonephritis, bilateral congenital cystic disease, pyelonephritis, hydronephrosis, glomerulosclerosis, lupus, amyloidosis, or periarteritis nodosa. In the case of hypertension accompanied by obvious renal disease, the renal origin of the hypertension has always been accepted, even though the ultimate cause of the elevated blood pressure is still unknown The nonspecific group would consist of those cases in which the cause is still unknown, so-called essential hypertension

PATHOGENESIS

If there is any single fact about the pathogenesis of true hypertension upon which all investigators are agreed, it is that the elevated diastolic blood pressure (the criterion of true hypertension) is due mainly to increased peripheral vascular resistance It is conceded also that such an increase of vascular resistance could occur only on the basis of either widespread obliterative organic disease, or spasm, of the smallest arteries and arterioles That the organic disease of the vessels is ever so severe and so widespread throughout the systemic circulation as to constitute a mechanical reason for increased peripheral vascular resistance is doubtful, so the ultimate cause, *in nearly all cases*, is mainly *functional*, i e, *generalized arteriolar vasospasm secondary either to neurogenic or to endocrinogenic or other humoral stimuli* Since the volume and viscosity of the blood remain constant under most conditions, the only possible variables which can affect the blood pressure are the force and output of the heart and the peripheral vascular resistance, and it is the adjustment between these variables which determines the final blood pressure In those cases in which an endocrine organ is involved, for example, peripheral arteriolar spasm caused by a specific pressor hormone has always been accepted as the main pathogenetic mechanism, although a direct effect upon the heart may also play a part. It is for the group classified as essential hypertension that even the site of the initiating pathologic change is not definitely established, and although vascular disease or some other pathologic process is found in the kidneys of almost 100 per cent of the patients with essential hypertension who come to autopsy, yet the *renal origin* of the hypertension has been strongly contested.

ESSENTIAL HYPERTENSION—THE BENIGN PHASE

By definition, the benign phase of essential hypertension signifies "persistently elevated blood pressure of unknown origin not accompanied by significant renal excretory functional disturbance" Because there is *no obvious* renal disease which can be determined clinically, there has been considerable resistance to the idea that this form of hypertension nevertheless may be of renal origin That other conditions may play a part has never been denied even by those who believe in its renal origin It is true that in a high percentage of the cases of human essential hypertension there is at least a *family history* of the condition. Inherited predisposition to elevated blood pressure is supposed to consist of an abnormal response of the arterioles to constricting stimuli; the cold-pressor test is one of the ways in which this has been determined. Of course, the inherited factor could also be the predisposition to the development of the arteriolar sclerosis, whatever the specific cause of that may be. It is certainly well established that in families in which the blood pressure of the parent is normal, the development of hypertension in the offspring is not nearly so frequent as in those in which both parents have had hypertension.

The indications are that *females are more frequently affected than males*. This is especially true for the malignant phase of hypertension, and may be accounted for by the much more common occurrence of other renal diseases complicating the existing renal vascular sclerosis Most prominent among these complicating renal diseases is *pyelonephritis*, especially in females, both in childhood and in

5

Mechanism of hypertension

HARRY GOLDBLATT

Systemic hypertension is an abnormal condition of great social and economic significance, mainly by reason of pathologic changes in the brain, heart, and kidneys resulting from the vascular disease associated with it. As an indirect cause of disability or death, it ranks first in the list of crippling conditions. True hypertension, which implies persistent elevation of diastolic as well as of systolic blood pressure, is one of the most common clinical signs of disease involving the cardiovascular system, and is perhaps the most frequent functional derangement of the body. In the United States, at least 50 per cent of persons over 50 years of age have hypertension of various origin and, directly or indirectly, elevated blood pressure plays a part in at least 25 per cent of all deaths in that age period. There is some indication that the trend is still upward.

HIGH BLOOD PRESSURE

The upper limits of blood pressure now considered normal are higher than those of 25 years ago. Today, a systolic blood pressure of 140 mm Hg and a diastolic pressure of 90 mm are generally accepted as the upper limits of normal for an adult of either sex, at age 40. Below and above this age, the trends are lower and higher, respectively. The elevation of the diastolic blood pressure is the more indicative of the state of true hypertension, but when there is an elevation of diastolic pressure, there is nearly always a corresponding elevation of the systolic pressure, to such a degree that there is also an increase of pulse pressure. There is such a thing as elevated systolic blood pressure alone, but it depends mainly upon increase of cardiac output and is not the result of increased peripheral vascular resistance. It occurs most commonly in association with endocrine disturbance, such as hyperthyroidism, with abnormal arteriovenous communication, or with arteriosclerosis limited to the aorta and large arteries, in all of which the "runoff" is normal. These are not examples of true hypertension, as defined above. Normally, the diastolic blood pressure is maintained at a certain level, mainly as a result of the intermittent input of blood into the vascular bed, and the resistance to the onflow of blood through the arterioles, i.e., the peripheral vascular resistance. Among the conditions which influence this relationship between the two are nervous stimuli which originate in various sites (carotid and aortic sinuses) and which influence the cardiac and vasomotor centers, endocrine secretions, and the natural tone of the peripheral arterioles.

CLASSIFICATION

Hypertension has been classified as primary and secondary, but, strictly speaking, the only circumstance in which the elevated blood pressure might well be considered *primary* would be if the increased peripheral vascular resistance were due only to an increase of the inherent tone of the arterioles. There is no other good reason for using the word "primary," unless it be in the sense of unknown origin, and for this the term "essential" has already been appropriated. Since peripheral vasospasm and the increased peripheral vascular resistance are nearly always caused by a

dog in 2 or 3 days, when hypertension and renal insufficiency are produced by excessive constriction of both main renal arteries In man, the malignant phase may occur as a result of pronounced obliterative arterial and arteriolar sclerosis, but more commonly it develops when excretory failure occurs as a result of the development of some complicating pathologic condition in a kidney which was previously the seat of arteriolar disease

The most common of these renal complications, the importance of which has not been stressed adequately because it is an insidious disease which is frequently overlooked clinically, is chronic interstitial nephritis (*pyelonephritis*) which, when sufficiently severe, brings about the excretory failure of kidneys, previously the seat of only arterial and arteriolar sclerosis. Other complicating renal diseases which may have the same effect as pyelonephritis are *glomerulonephritis*, *glomerulosclerosis*, the glomerular lesions of *lupus*, *periarteritis nodosa*, and *amyloidosis*, which when superimposed upon renal arterial and arteriolar sclerosis of even moderate degree, bring about the malignant phase Less commonly, the malignant phase occurs as a result of the development of arteriolosclerosis in an individual with a previously existent chronic bilateral pyelonephritis The importance of the part played by *interstitial nephritis* as one of the possible causes of malignant hypertension cannot be stressed too greatly, because it promises possible treatment, and even prevention, of the most common pathologic condition responsible for bringing about the change from the benign to the malignant phase of essential hypertension

EXPERIMENTAL RENAL HYPERTENSION

On the basis that the development of obliterative vascular disease precedes the occurrence of essential hypertension in man, and that the elevation of the blood pressure does not occur until, and unless, the kidneys are involved, experiments were devised by the author to test whether or not the vascular disease alone could be the primary factor in the elevation of the blood pressure Because it was not possible to reproduce the arterial and arteriolar sclerosis, it was decided to constrict the main renal arteries, in the hope that this procedure might reproduce the disturbance of intrarenal hemodynamics which undoubtedly results from the intrarenal vascular disease.

In the dog, moderate constriction of only one main renal artery by means of a silver clamp devised for the purpose resulted in an elevation of blood pressure which began within 24 hr, increased for a week or longer, remained elevated at the maximum level for about 2 or 3 weeks, and then usually returned to normal in about 4 to 6 weeks. Only rarely did it remain elevated much longer. In the rat, the rabbit, the sheep, and the goat, however, it remained elevated for many months. The removal of the ischemic kidney at the height of the hypertension resulted in a prompt fall of the blood pressure to normal The development of elevated blood pressure as a result of constriction of only *one* main renal artery, and the prompt return of the blood pressure to normal when the ischemic kidney was removed, led to the recognition of the existence of cases of human hypertension associated with *unilateral renal disease* and the return of the blood pressure to normal as a result of the removal of the diseased kidney in those cases in which the contralateral kidney proved to be normal Homer Smith (1956), in a review of the literature up to the end of 1956, reported a cure of the hypertension in 149 out of 575 cases (26 per cent) of essential hypertension in which the existence of unilateral renal disease was recognized and the diseased kidney was removed Thompson, in a report of similar cases operated upon at the Mayo Clinic, reported a cure of the hypertension in 50 per cent of the patients with unilateral renal disease, when the renal disease proved to be an atrophic kidney, probably the seat of vascular disease and pyelonephritis It does not seem [illegible]

…this was not recognized.

Moderate constriction of *both* main renal arteries, or moderate constriction of one main renal artery and contralateral nephrectomy, resulted in the development of persistent hypertension in animals. The successful production of persistent hypertension, first in the dog, and later in a variety of animals, by a

adult life, most frequently in association with pregnancy.

In so far as age is concerned, there are data which show definitely that the trend after the age of 40 years is upward and that the incidence of essential hypertension is relatively low before 40.

Although hypertension usually is considered to be of infrequent occurrence in Orientals and in African Negroes, yet the incidence of hypertension in the pure Negro of the Virgin Islands, for example, is unusually high. It may be of special interest that in the kidneys of two patients from these islands with so-called essential hypertension, which the author had an opportunity to examine, there was severe diffuse intrarenal, especially preglomerular, arteriolar sclerosis. The effect of *environment* is intangible, and although much has been written about psychoneurogenic effects of the *stress* of modern living conditions, yet it is almost impossible to establish with certainty any direct relationship between these and the peripheral vascular disease or the persistent hypertension. At autopsy, in cases of human, benign, essential hypertension, arterial and arteriolar sclerosis is present in many organs and in variable amount, but it has been shown that it is most pronounced and most frequent *in the kidneys* of such individuals, although it has been demonstrated clearly also that the kidney is the organ least vulnerable to vascular sclerosis. Most investigators, at least prior to 1930, have interpreted this to mean that the elevated blood pressure comes first and that the vascular disease in all tissues, including the kidneys, is a consequence of the persistent stretching of the wall of the blood vessels by the elevated intravascular pressure, or the result of persistent vasospasm On the contrary, the author's interpretation is that the hypertension does not develop until the kidneys are involved, whatever the cause of the vascular disease may be.

ESSENTIAL HYPERTENSION—MALIGNANT PHASE

The most recent acceptable definition of malignant hypertension (Medical Advisory Board of the Council for High Blood Pressure of the American Heart Association) reads as follows.

A clinical phase, rarely occurring *de novo*, more often appearing after a primary or secondary hypertension, characterized by diastolic hypertension and by accelerated and progressive renal damage, usually (but not necessarily) accompanied by papilledema, often by retinal hemorrhages and "exudate" and giving rise to death from uremia, unless the course is terminated along the way by complicating brain or heart damage.

There have been great differences of opinion about the pathogenesis of this phase of hypertension. Some consider it to be a form of essential hypertension, not primarily of renal origin but marked by impairment of renal excretory function which occurs as a late or terminal manifestation; others (including the author) believe that the malignant phase, like the benign, is primarily, and even more obviously, of renal origin. There are good reasons, experimental, pathologic, and clinical, for this wide difference of view. A chief reason has been the failure of many investigators to recognize that the pathologic changes in the kidneys in the malignant phase are neither uniform nor unique. Another reason has been the difference of opinion about the nature and the pathogenesis of the necrotizing arteriolar lesion which has been regarded as pathognomonic of this condition.

A common error has been the belief that the *arteriolar fibrinoid degeneration and necrosis*, with or without perivascular inflammation, usually considered pathognomonic of malignant hypertension, represent an accelerated form of arteriolosclerosis There are no morphologic or pathogenetic reasons for the confusion of this lesion with arteriolosclerosis Another belief has been that arteriolar necrosis is so diffuse and so severe in the kidneys that it is actually the cause of the renal failure, when it develops in a person with previously benign hypertension This belief is not based upon substantial evidence As a matter of fact the arteriolar necrosis involving the kidneys is a sporadic, variable, secondary, and usually terminal manifestation of the malignant phase of essential hypertension It is sometimes difficult to find any of these lesions, although occasionally they may be abundant. Exactly what it is that brings about the fibrinoid necrosis of previously normal or sclerotic arterioles is not known It can develop in the arterioles of the

dog in 2 or 3 days, when hypertension and renal insufficiency are produced by excessive constriction of both main renal arteries. In man, the malignant phase may occur as a result of pronounced obliterative arterial and arteriolar sclerosis, but more commonly it develops when excretory failure occurs as a result of the development of some complicating pathologic condition in a kidney which was previously the seat of arteriolar disease

The most common of these renal complications, the importance of which has not been stressed adequately because it is an insidious disease which is frequently overlooked clinically, is chronic interstitial nephritis (*pyelonephritis*) which, when sufficiently severe, brings about the excretory failure of kidneys, previously the seat of only arterial and arteriolar sclerosis Other complicating renal diseases which may have the same effect as pyelonephritis are *glomerulonephritis*, *glomerulosclerosis*, the glomerular lesions of *lupus*, *periarteritis nodosa*, and *amyloidosis*, which when superimposed upon renal arterial and arteriolar sclerosis of even moderate degree, bring about the malignant phase Less commonly, the malignant phase occurs as a result of the development of arteriolosclerosis in an individual with a previously existent chronic bilateral pyelonephritis The importance of the part played by *interstitial nephritis* as one of the possible causes of malignant hypertension cannot be stressed too greatly, because it promises possible treatment, and even prevention, of the most common pathologic condition responsible for bringing about the change from the benign to the malignant phase of essential hypertension.

EXPERIMENTAL RENAL HYPERTENSION

On the basis that the development of obliterative vascular disease precedes the occurrence of essential hypertension in man, and that the elevation of the blood pressure does not occur until, and unless, the kidneys are involved, experiments were devised by the author to test whether or not the vascular disease alone could be the primary factor in the elevation of the blood pressure Because it was not possible to reproduce the arterial and arteriolar sclerosis, it was decided to constrict the main renal arteries, in the hope that this procedure might reproduce the disturbance of intrarenal hemodynamics which undoubtedly results from the intrarenal vascular disease.

In the dog, moderate constriction of only one main renal artery by means of a silver clamp devised for the purpose resulted in an elevation of blood pressure which began within 24 hr, increased for a week or longer, remained elevated at the maximum level for about 2 or 3 weeks, and then usually returned to normal in about 4 to 6 weeks. Only rarely did it remain elevated much longer. In the rat, the rabbit, the sheep, and the goat, however, it remained elevated for many months The removal of the ischemic kidney at the height of the hypertension resulted in a prompt fall of the blood pressure to normal. The development of elevated blood pressure as a result of *constriction of only one* main renal artery, and the prompt return of the blood pressure to normal when the ischemic kidney was removed, led to the recognition of the existence of cases of human hypertension associated with *unilateral renal disease* and the return of the blood pressure to normal as a result of the removal of the diseased kidney in those cases in which the contralateral kidney proved to be normal. Homer Smith (1956), in a review of the literature up to the end of 1956, reported a cure of the hypertension in 149 out of 575 cases (26 per cent) of essential hypertension in which the existence of unilateral renal disease was recognized and the diseased kidney was removed. Thompson, in a report of similar cases operated upon at the Mayo Clinic, reported a cure of the hypertension in 50 per cent of the patients with unilateral renal disease, when the renal disease proved to be an atrophic kidney, probably the seat of vascular disease and pyelonephritis It does not seem unreasonable to suggest that in many, if not all, of the cases in which the blood pressure failed to return to normal, the other kidney was also diseased, although this was not recognized.

Moderate constriction of both main renal arteries, or moderate constriction of one main renal artery and contralateral nephrectomy, resulted in the development of persistent hypertension in animals. The successful production of persistent hypertension, first in the dog, and later in a variety of animals, by a

method which most closely simulates the probable hemodynamic state of the kidney of essential hypertension, confirmed the assumption that it is the intrarenal vascular disease which causes human essential hypertension. The fact that, as in human essential hypertension, a disturbance of renal excretory function was not a necessary accompaniment of this type of experimental hypertension is considered additional important, indeed essential, evidence for the possible identity of these hypertensive states in man and the experimental animal The nature of the hemodynamic disturbance produced in a kidney by moderate constriction of a main renal artery has not been determined with certainty in all stages of the hypertension which results from this procedure, but it is probably similar to that of the nephrosclerotic kidney so frequently found at autopsy in cases of human essential hypertension By direct means, immediately after constriction of the main renal artery in the dog, it was shown that there was definite reduction in the blood flow through the kidney, and, by indirect means (inulin clearance), it has been shown that the reduction of renal blood flow, without reduction, or even with an actual increase, of intraglomerular pressure, and with maintenance of normal excretory function, can be found in most individuals with early benign human essential hypertension The results of the large number of investigations carried out after the successful production of experimental renal hypertension in animals indicate that human essential hypertension also may be of renal origin The main reasons in favor of this view may be summarized briefly as follows

SUMMARY OF THE EVIDENCE IN FAVOR OF THE RENAL ORIGIN OF HUMAN ESSENTIAL HYPERTENSION

In most cases of human essential hypertension, there is found at autopsy either renal arterial and arteriolar sclerosis only (the unscarred kidney), or true nephrosclerosis (the scarred kidney), or some other obvious extrarenal or intrarenal lesion which probably produces the same hemodynamic disturbance in the kidney as is produced by intrarenal obliterative vascular sclerosis This is true despite the fact that, of all organs in the body, the vascular bed of the kidney is the least vulnerable to the development of arteriolosclerosis

In animals, it is possible to constrict both main renal arteries just enough to bring about the development of hypertension without significant impairment of renal excretory function. Even moderate constriction of one main renal artery and contralateral nephrectomy may be followed by the development of persistent hypertension without significant impairment of renal excretory function.

In most patients with benign essential hypertension, there is some reduction of the flow of blood through the glomeruli, similar to that produced by moderate constriction of the main renal artery in hypertensive animals.

Great constriction, without occlusion, of both main renal arteries, or great constriction of one main renal artery and contralateral nephrectomy or contralateral occlusion of the ureter, results in elevation of blood pressure, definite impairment of renal excretory function, and the development of the necrotizing arteriolar lesions characteristic of the malignant phase of essential hypertension.

Hemodynamically, the state of an animal with experimental renal hypertension, in both the benign and malignant phases, is in all respects like that of the corresponding phases of human essential hypertension In animals, moderate constriction of the main artery of one kidney results in a rise of blood pressure which, in the dog, usually persists for from 4 to 6 weeks, but which in the rat, rabbit, sheep, and goat may persist for many months In man, also, partial obstruction of the main artery of only one kidney by an embolus or thrombus, or by pressure upon, or kinking of, the main renal artery, has been followed by the development of persistently elevated blood pressure

In animals with benign hypertension for as long as 8 years, the only significant anatomic alterations found at autopsy have been moderate cardiac hypertrophy and medial thickening of the arteries and arterioles due to hypertrophy and hyperplasia of the smooth muscle cells Simple intimal arteriosclerosis or hyalinizing arteriolar sclerosis did not develop in animals as a result of pronounced hypertension for many years Cardiac failure, coronary thrombosis, and cerebral hemorrhage did not occur in animals, for they did not develop coronary or cerebral arteriosclerosis. This is an indication that in man the vascular disease

probably precedes the development of the persistent hypertension, which happens only when the kidneys also become the seat of arterial and arteriolar sclerosis. This does not ignore or exclude the fact that, at least in some human beings, the labile type of neurogenic or endocrinogenic elevation of blood pressure may *occur* before the fixed and persistent hypertension develops as a result of the vascular disease of the kidneys. This is not to say that the vascular disease is a direct consequence of the previously elevated blood pressure. The contention of Byrom and Dodson that hypertension alone can produce even the necrotizing arteriolar lesion of the malignant phase of hypertension has not been confirmed. There is *no proof that* psychoneurogenic hypertension actually plays a part in the pathogenesis of the vascular disease in man, or that it is a necessary precedent of essential hypertension.

In many cases in which a diagnosis of essential hypertension had been entertained at first, the occasional existence of unilateral renal disease has now been recognized. The fall of the blood pressure which has resulted from the removal of the diseased kidney or restoration of the normal circulation to the kidney can be explained only on the basis that the kidney—the victim of either vascular sclerosis or some other abnormal condition which produces the same intrarenal hemodynamic disturbance—is the source of a substance which, in some way, induces the development of the hypertension.

Aortograms in the living patient, and careful investigation of the renal arteries and aorta at the site of origin of the renal arteries, at autopsy, have revealed stenosis in various portions of one of the main renal arteries, or in both of them, including their site of origin from the aorta, as a result of atherosclerosis, *simple* intimal fibrosis, or fibroelastosis, in cases otherwise regarded clinically as typical examples of human essential hypertension. These lesions have the effect of a clamp on the renal artery, in so far as the kidney is concerned. In some cases of this kind in which the vascular abnormality has been recognized in life, excision of the involved portion of the blood vessels and transplantation of the arteries, or the insertion of an arterial graft have been used to restore the circulation to such a kidney or kidneys, and the elevated blood pressure has returned to normal when there was no significant intrarenal arterial or arteriolar disease, or any other pronounced pathologic process within the kidney.

In experimental renal hypertension, all evidence is in favor of a humoral mechanism of renal origin as the cause of the elevated blood pressure.

Renin, an enzyme from the kidney, acts upon *angiotensinogen*, the substrate in the plasma, to produce *angiotensin*, a polypeptide, which is the effective vasoconstrictor substance that induces the vasospasm and an increase in peripheral vascular resistance. An increased amount of this substance has been *demonstrated* in the blood of hypertensive man and animals. But in animals with experimental renal hypertension for years, and in human beings in the chronic benign phase, there is only a slightly elevated angiotensin content in the blood, although, even at this late stage, the blood pressure of hypertensive animals can be brought down to normal by the parenteral injection of *renin* and the production of an adequate quantity of *antirenin* in the blood. This has not been possible in man because, with the exception of the *renin* of monkeys and anthropoid apes, no heterologous antirenin will inactivate human renin.

In *hypertensive* dogs, the development of accessory circulation to the kidneys by their transplantation into the spleen, or by wrapping them in omentum or muscle, results in a fall of blood pressure to normal. In human hypertension, however, this procedure probably would not be effective because the obliterative vascular disease is almost always intrarenal, therefore the production of accessory circulation through the cortex in hypertensive human beings would probably not improve the circulation of the functioning components of the kidney.

There is no convincing evidence that hypertension, *per se*, is the cause of arterial or arteriolar sclerosis in the brain, heart, and kidney, but it is recognized that the existence of hypertension in an individual with vascular disease greatly jeopardizes life. Cardiac failure and rupture of a myocardial infarct are more likely to occur in a hypertensive individual who develops occlusive coronary disease. Similarly, cerebral hemorrhage is more likely to occur in a hypertensive person with cerebral vascular sclerosis. Aneurysms of an arteriosclerotic aorta and of large vessels are also more

method which most closely simulates the probable hemodynamic state of the kidney of essential hypertension, confirmed the assumption that it is the intrarenal vascular disease which causes human essential hypertension. The fact that, as in human essential hypertension, a disturbance of renal excretory function was not a necessary accompaniment of this type of experimental hypertension is considered additional important, indeed essential, evidence for the possible identity of these hypertensive states in man and the experimental animal. The nature of the hemodynamic disturbance produced in a kidney by moderate constriction of a main renal artery has not been determined with certainty in all stages of the hypertension which results from this procedure, but it is probably similar to that of the nephrosclerotic kidney so frequently found at autopsy in cases of human essential hypertension. By direct means, immediately after constriction of the main renal artery in the dog, it was shown that there was definite reduction in the blood flow through the kidney, and, by indirect means (inulin clearance), it has been shown that the reduction of renal blood flow, without reduction, or even with an actual increase, of intraglomerular pressure, and with maintenance of normal excretory function, can be found in most individuals with early benign human essential hypertension The results of the large number of investigations carried out after the successful production of experimental renal hypertension in animals indicate that human essential hypertension also may be of renal origin The main reasons in favor of this view may be summarized briefly as follows

SUMMARY OF THE EVIDENCE IN FAVOR OF THE RENAL ORIGIN OF HUMAN ESSENTIAL HYPERTENSION

In most cases of human essential hypertension, there is found at autopsy either renal arterial and arteriolar sclerosis only (the unscarred kidney), or true nephrosclerosis (the scarred kidney), or some other obvious extrarenal or intrarenal lesion which probably produces the same hemodynamic disturbance in the kidney as is produced by intrarenal obliterative vascular sclerosis This is true despite the fact that, of all organs in the body, the vascular bed of the kidney is the least vulnerable to the development of arteriolosclerosis

In animals, it is possible to constrict both main renal arteries just enough to bring about the development of hypertension without significant impairment of renal excretory function. Even moderate constriction of one main renal artery and contralateral nephrectomy may be followed by the development of persistent hypertension without significant impairment of renal excretory function.

In most patients with benign essential hypertension, there is some reduction of the flow of blood through the glomeruli, similar to that produced by moderate constriction of the main renal artery in hypertensive animals

Great constriction, without occlusion, of both main renal arteries, or great constriction of one main renal artery and contralateral nephrectomy or contralateral occlusion of the ureter, results in elevation of blood pressure, definite impairment of renal excretory function, and the development of the necrotizing arteriolar lesions characteristic of the malignant phase of essential hypertension.

Hemodynamically, the state of an animal with experimental renal hypertension, in both the benign and malignant phases, is in all respects like that of the corresponding phases of human essential hypertension. In animals, moderate constriction of the main artery of one kidney results in a rise of blood pressure which, in the dog, usually persists for from 4 to 6 weeks, but which in the rat, rabbit, sheep, and goat may persist for many months In man, also, partial obstruction of the main artery of only one kidney by an embolus or thrombus, or by pressure upon, or kinking of, the main renal artery, has been followed by the development of persistently elevated blood pressure

In animals with benign hypertension for as long as 8 years, the only significant anatomic alterations found at autopsy have been moderate cardiac hypertrophy and medial thickening of the arteries and arterioles due to hypertrophy and hyperplasia of the smooth muscle cells Simple intimal arteriosclerosis or hyalinizing arteriolar sclerosis did not develop in animals as a result of pronounced hypertension for many years Cardiac failure, coronary thrombosis, and cerebral hemorrhage did not occur in animals, for they did not develop coronary or cerebral arteriosclerosis. This is an indication that in man the vascular disease

probably precedes the development of the persistent hypertension, which happens only when the kidneys also become the seat of arterial and arteriolar sclerosis. This does not ignore or exclude the fact that, at least in some human beings, the labile type of neurogenic or endocrinogenic elevation of blood pressure may occur before the fixed and persistent hypertension develops as a result of the vascular disease of the kidneys. This is not to say that the vascular disease is a direct consequence of the previously elevated blood pressure. The contention of Byrom and Dodson that hypertension alone can produce even the necrotizing arteriolar lesion of the malignant phase of hypertension has not been confirmed. There is no proof that psychoneurogenic hypertension actually plays a part in the pathogenesis of the vascular disease in man, or that it is a necessary precedent of essential hypertension

In many cases in which a diagnosis of essential hypertension had been entertained at first, the occasional existence of unilateral renal disease has now been recognized The fall of the blood pressure which has resulted from the removal of the diseased kidney or restoration of the normal circulation to the kidney can be explained only on the basis that the kidney—the victim of either vascular sclerosis or some other abnormal condition which produces the same intrarenal hemodynamic disturbance—is the source of a substance which, in some way, induces the development of the hypertension

Aortograms in the living patient, and careful investigation of the renal arteries and aorta at the site of origin of the renal arteries, at autopsy, have revealed stenosis in various portions of one of the main renal arteries, or in both of them, including their site of origin from the aorta, as a result of atherosclerosis, simple intimal fibrosis, or fibroelastosis, in cases otherwise regarded clinically as typical examples of human essential hypertension These lesions have the effect of a clamp on the renal artery, in so far as the kidney is concerned In some cases of this kind in which the vascular abnormality has been recognized in life, excision of the involved portion of the blood vessels and transplantation of the arteries, or the insertion of an arterial graft, have been used to restore the circulation to such a kidney or kidneys, and the elevated blood pressure has returned to normal when there was no significant intrarenal arterial or arteriolar disease, or any other pronounced pathologic process within the kidney.

In experimental renal hypertension, all evidence is in favor of a humoral mechanism of renal origin as the cause of the elevated blood pressure.

Renin, an enzyme from the kidney, acts upon *angiotensinogen*, the substrate in the plasma, to produce *angiotensin*, a polypeptide, which is the effective vasoconstrictor substance that induces the vasospasm and an increase in peripheral vascular resistance. An increased amount of this substance has been demonstrated in the blood of hypertensive man and animals. But in animals with experimental renal hypertension for years, and in human beings in the chronic benign phase, there is only a slightly elevated angiotensin content in the blood, although, even at this late stage, the blood pressure of hypertensive animals can be brought down to normal by the parenteral injection of renin and the production of an adequate quantity of *antirenin* in the blood. This has not been possible in man because, with the exception of the renin of monkeys and anthropoid apes, no heterologous antirenin will inactivate human renin.

In hypertensive dogs, the development of accessory circulation to the kidneys by their transplantation into the spleen, or by wrapping them in omentum or muscle, results in a fall of blood pressure to normal In human hypertension, however, this procedure probably would not be effective because the obliterative vascular disease is almost always intrarenal, therefore the production of accessory circulation through the cortex in hypertensive human beings would probably not improve the circulation of the functioning components of the kidney.

There is no convincing evidence that hypertension, per se, is the cause of arterial or arteriolar sclerosis in the brain, heart, and kidney, but it is recognized that the existence of hypertension in an individual with vascular disease greatly jeopardizes life. Cardiac failure and rupture of a myocardial infarct are more likely to occur in a hypertensive individual who develops occlusive coronary disease Similarly, cerebral hemorrhage is more likely to occur in a hypertensive person with cerebral vascular sclerosis Aneurysms of an arteriosclerotic aorta and of large vessels are also more

method which most closely simulates the probable hemodynamic state of the kidney of essential hypertension, confirmed the assumption that it is the intrarenal vascular disease which causes human essential hypertension. The fact that, as in human essential hypertension, a disturbance of renal excretory function was not a necessary accompaniment of this type of experimental hypertension is considered additional important, indeed essential, evidence for the possible identity of these hypertensive states in man and the experimental animal. The nature of the hemodynamic disturbance produced in a kidney by moderate constriction of a main renal artery has not been determined with certainty in all stages of the hypertension which results from this procedure, but it is probably similar to that of the nephrosclerotic kidney so frequently found at autopsy in cases of human essential hypertension. By direct means, immediately after constriction of the main renal artery in the dog, it was shown that there was definite reduction in the blood flow through the kidney, and, by indirect means (inulin clearance), it has been shown that the reduction of renal blood flow, without reduction, or even with an actual *increase*, of intraglomerular pressure, and *with maintenance* of normal excretory function, can be found in most individuals with early *benign* human essential hypertension The results of the large number of investigations carried out after the successful production of experimental renal hypertension in animals indicate that human essential hypertension also may be of renal origin The main reasons in favor of this view may be summarized briefly as follows

SUMMARY OF THE EVIDENCE IN FAVOR OF THE RENAL ORIGIN OF HUMAN ESSENTIAL HYPERTENSION

In most cases of human essential hypertension, there is found at autopsy either renal arterial and arteriolar sclerosis only (the unscarred kidney), or true nephrosclerosis (the scarred kidney), or some other obvious extrarenal or intrarenal lesion which probably produces the same hemodynamic disturbance in the kidney as is produced by intrarenal obliterative vascular sclerosis. This is true despite the fact that, of all organs in the body, the vascular bed of the kidney is the least vulnerable to the development of arteriolosclerosis.

In animals, it is possible to constrict both main renal arteries just enough to bring about the development of hypertension without significant impairment of renal excretory function. Even moderate constriction of one main renal artery and contralateral nephrectomy may be followed by the development of persistent hypertension without significant impairment of renal excretory function.

In most patients with benign essential hypertension, there is some reduction of the flow of blood through the glomeruli, similar to that produced by moderate constriction of the main renal artery in hypertensive animals.

Great constriction, without occlusion, of both main renal arteries, or great constriction of one main renal artery and contralateral nephrectomy or contralateral occlusion of the ureter, results in elevation of blood pressure, definite impairment of renal excretory function, and the development of the necrotizing arteriolar lesions characteristic of the malignant phase of essential hypertension.

Hemodynamically, the state of an animal with experimental renal hypertension, in both the benign and malignant phases, is in all respects like that of the corresponding phases of human essential hypertension. In animals, moderate constriction of the main artery of one kidney results in a rise of blood pressure which, in the dog, usually persists for from 4 to 6 weeks, but which in the rat, rabbit, sheep, and goat may persist for many months. In man, also, partial obstruction of the main artery of only one kidney by an embolus or thrombus, or by pressure upon, or kinking of, the main renal artery, has been followed by the development of persistently elevated blood pressure

In animals with benign hypertension for as long as 8 years, the only significant anatomic alterations found at autopsy have been moderate cardiac hypertrophy and medial thickening of the arteries and arterioles due to hypertrophy and hyperplasia of the smooth muscle cells Simple intimal arteriosclerosis or hyalinizing arteriolar sclerosis did not develop in animals as a result of pronounced hypertension for many years Cardiac failure, coronary thrombosis, and cerebral hemorrhage did not occur in animals, for they did not develop coronary or cerebral arteriosclerosis. This is an indication that in man the vascular disease

Clinical aspects of hypertension

RUSTOM JAL VAKIL

Prevalence. The high incidence and importance of high blood pressure, or hypertension, in the causation of death and disease remain unquestioned. Next to arteriosclerosis, it is the disease with the greatest fatality rate, accounting directly or indirectly for over one-fifth of all deaths and for 25 to 35 per cent of deaths over the age of 50. In the United States alone, it is responsible for over 320,000 deaths per year.

There is no unanimity of opinion, however, about the exact *incidence of hypertension.* Even in the United States, the total number of hypertensive persons has been computed by different observers as 20 million, 15 million, and 6 million, respectively (Robinson and Brucer, 1939). This discrepancy between different estimates is due not to error but to the different criteria adopted in the selection of cases. The borderline between normotensive and hypertensive zones has not as yet been clearly defined.[1]

Hypertension, either primary or secondary, occurs in from 5 to 20 per cent of the entire population, and in over 50 per cent of individuals over the age of 50. Its true incidence is probably higher than that reported in clinical studies, since many cases are completely asymptomatic and blood pressure is not routinely measured. Moreover, many practitioners withhold true figures of blood pressure levels from patients and relatives for fear of causing a "hypertension neurosis."

In most civilized countries, hypertension is one of the most common causes of heart disease, as well as of heart failure, accounting roughly for about 30 per cent of all cardiac patients. In Eastern countries, the incidence of hypertension is probably as high as in Western countries, although severe and malignant forms of the disease are much less common (Vakil, 1950).

Definition. The term *hypertension* or *high blood pressure* connotes a *systemic arterial* pressure consistently above the accepted *normal.* In the past, it was customary to regard all blood pressure readings over 150 systolic and over 90 diastolic as indicative of hypertension (Hines, 1940, Herndon, 1946). In view of the *great influence* of age and sex factors on blood pressure, as demonstrated conclusively by recent observers (Bussek et al., 1946; Gover, 1948, Master et al., 1952), such fixed and unvarying *criteria* for normal blood pressure levels are no longer acceptable.

A blood pressure reading higher than the statistically established average or mean level *need not* be abnormal; it may still be within the normal or physiologic range for the age and sex of the patient. The term *hypertension* must therefore be restricted to levels consistently *higher than the normal maximum level* (NML) rather than the *average or mean level* for a given age and sex. The difference between the recorded high blood pressure level and the maximum *normal level* gives a rough measure of the degree of hypertension and has been termed "pressure load" or "plus pressure" (Vakil, 1954b).

Arterial hypertension is merely a physical finding or sign, like fever or tachycardia, that may result from a variety of disorders. As such, it means no more than an abnormally high

[1] See also Part 3, Chap. 5. *Editor.*

likely to occur in the hypertensive individual. These lesions do not occur in the hypertensive animals because they do not develop the arteriosclerosis.

The only proved secondary changes which occur in any organ directly as a result of elevated blood pressure, in the hypertensive animals, and even in man, are *hypertrophy of the heart* and *thickening of the media* of the arteries. Although there is no proof that the elevated blood pressure per se can initiate and produce arterial sclerosis and arteriolar sclerosis, and indeed there is proof to the contrary, yet there is no unequivocal evidence that when the other condition, or conditions, responsible for the sclerosis is present, the elevated blood pressure may not aggravate or accelerate the sclerosis.

Hypertension accompanied by impairment of renal excretory function (the malignant phase) can occur as a direct result of pronounced obliterative arterial and arteriolar sclerosis, but it occurs more commonly as a result of some other complicating disease of the kidney, notably chronic pyelonephritis, which develops in a kidney already the seat of arterial and arteriolar sclerosis. In animals, this phase can be reproduced by great constriction of the main renal arteries.

It is difficult to avoid the conclusion that the so-called essential hypertension, in both the benign and malignant phases, is of renal origin

disease and ventricular hypertrophy was proved more conclusively by Traube (1856) with the aid of pulse palpation.

Among the complications of hypertension, apoplexy or, cerebral hemorrhage, was first described by Wepfer (1658) in a gouty monk "inclined to anger"; coronary thrombosis, by Bonetus (1700) and by Krehl (1740). The signs of left ventricular hypertrophy in hypertension were described by Laennec (1819), and the high-tension pulse and loud aortic 2d sound of hypertension, by Traube.

The first sphygmomanometer for measuring blood pressure was designed by Herisson in 1830, to be later refined and modified by a host of workers, including von Basch (1893), Potain, and Riva-Rocci (1896), thus inaugurating a new era in the understanding of circulatory hemodynamics

After the pioneer work of Richard Bright, it was customary to regard hypertension as a consequence of either kidney disease or arteriosclerosis, that is, until Mahomed described it as a *precursor* of Bright's disease and von Basch referred to it as *latent arteriosclerosis* The present concept of essential hypertension as an independent entity, not necessarily followed by renal or arterial disease, was developed by Allbutt and Huchard

Another milestone in our growth of knowledge of hypertension was the chemicopathologic study and the classification of nephrosclerosis into benign and malignant forms (Volhard and Fahr, 1914).

Since the introduction of an ancient Indian plant (*Rauwolfia serpentina*) into the Western world (by the author, 1949), immense strides have been made and considerable headway has been gained in the treatment of high blood pressure. Hypertension was once given up as hopelessly irremediable, now innumerable patients with hypertension have been benefited, and at times given a new lease on life, by the introduction of many new antihypertensive remedies, particularly the ganglion-blocking agents and the chlorothiazide derivatives

Pathogenesis HEMODYNAMIC MECHANISMS. Several mechanisms are concerned in the maintenance of normal blood pressure and circulatory homeostasis Functional changes of one or more of these dynamic factors can bring about a transitory or persistent rise of systemic blood pressure: (1) increased cardiac output or minute volume, (2) increased viscosity of the blood, (3) decreased elas-ticity of the ... the blo...

After ... finally established that in the great majority of cases of essential hypertension, the mechan... concerned ... by vaso... ganic n... once postulated by Gull and Sutton in the genesis of hypertension, has been convincingly ruled out.

CAUSE OF VASOCONSTRICTION. The exact nature of the stimulus or factor that brings about the angiospasm remains obscure. It has not as yet been convincingly established whether it is due to excess of a circulating pressor substance (humoral theory), lack of depressor substance (humoral theory), neurogenic reflex mechanism, or increased reactivity of the arterioles (possibly secondary to organic changes), which have become hypersensitive to normal amounts of pressor substance. It is possible that the *initiating mechanism* may not be the same as the *perpetuating mechanism*. It is not even certain whether essential hypertension is a single clinical entity or a collection of entities grouped under one heading

PRESSOR MECHANISMS Since the time of Bright, medical opinion regarding the etiology of hypertension has been constantly vacillating between the theories of renal and extrarenal *origin*. *First* regarded as renal in origin, on the basis of Bright's work, hypertension was then considered to be primary and nonrenal after the studies of Allbutt and Huchard. Goldblatt's experiments with clamping of the renal *arteries of dogs* seemed to substantiate the "renal" theory. More recent studies, however, have again cast doubts on the role of the kidney. Of the many pressor mechanisms implicated in the genesis of essential *hypertension, the following* are of particular interest, according to Fishberg (1954)

THEORIES OF ORIGIN

1. Renal
   - *a*. Renin-angiotensin pressor mechanism (Goldblatt, 1937; Braun-Menéndez, 1939, Page, 1939)
   - *b* Disturbed balance of vasoexciter and vasodepressor mechanisms (Shorr)
   - *c* Juxtaglomerular apparatus (Polkissen) mechanism (Goormaghtigh)
   - *d*. Intrarenal pelvis mechanism (Ravich)
   - *e* Deficiency of antipressor renal principle
2. Peripheral (humoral)
   - *a*. Pressor substance in blood, e g, pherentasin (Schroeder)
   - *b*. Sensitization of arterioles to normal pressor substance
   - *c* Intrinsic alteration of arteriolar wall
3. Endocrine (or glandular)
   - *a* Hypernorepinephrinemia (medullary oversecretion)
   - *b* Overaction of adrenal cortex (hyperadrenocorticism)
   - *c* Pituitary overaction
   - *d*. Gonadal dysfunction
   - *e* Thyroid dysfunction
   - *f* Pancreatic disorder

level of pressure or the exaggeration of a normal biologic phenomenon. When associated, however, with clinical or pathologic manifestations of disease, it should be referred to as *hypertensive disease* or *hypertensive heart disease* (cardiopathy), renal disease (nephropathy), or cerebral disease (encephalopathy), depending on the site of maximum involvement.

True hypertension (arterial or systemic hypertension) implies an elevation of both the systolic and the diastolic blood pressure. When the rise of either pressure happens to be disproportionate, the condition is referred to as either *systolic* or *diastolic* hypertension.

Systolic Hypertension. An isolated elevation of systolic pressure, the diastolic remaining normal or low, is referred to as systolic hypertension. Hemodynamically distinct from true hypertension, it may be of cardiac or aortic origin.

CAUSES

- I. Cardiac (increased left ventricular stroke volume)
  - *A.* Aortic regurgitation
  - *B.* Patent ductus arteriosus
  - *C.* Arteriovenous fistula or aneurysm
  - *D.* Complete heart block
  - *E.* Thyrotoxicosis
  - *F.* Severe anemia
  - *G.* Beriberi
  - *H.* Paget's disease
- II. Aortic (decreased elasticity or distensibility of aorta)
  - *A.* Senile changes of aortic wall
  - *B.* Atherosclerosis or aorta
  - *C.* Coarctation of aorta

The differentiation of systolic from true or diastolic hypertension is of great importance for diagnosis, prognosis, and treatment. A transitory rise of blood pressure, usually systolic, during or after intense emotion (e.g., excitement) or exercise is commonly referred to as *physiologic hypertension*.

Types of Hypertension. Persistent elevation of diastolic and systolic blood pressure levels, in the absence of any demonstrable cause, is referred to as *essential or primary hypertension*. When secondary to an obvious cause or lesion, it is referred to as *secondary or symptomatic hypertension*. Unfortunately, 80 to 90 per cent of cases are of the essential type, the causes remaining obscure in spite of all investigations.

ETIOLOGIC CLASSIFICATION OF HYPERTENSION

- I. *Essential (or primary)*
  - *A.* Benign (about 90 per cent)
  - *B.* Malignant (about 10 per cent)
- II. Secondary (or symptomatic)
  - *A.* Renal (or nephrogenic)
  - *B.* Endocrine
  - *C.* Neurogenic (or cerebral)
  - *D.* Psychogenic
  - *E.* Cardiovascular
  - *F.* Miscellaneous

ESSENTIAL HYPERTENSION

Nomenclature. One of the most frequent causes of death, essential hypertension has been discussed in the medical literature under a variety of designations (Fishberg, 1954), including primary hypertension, benign or malignant sclerosis (Volhard and Fahr), hyperpiesia (Allbutt), presclerosis (Huchard), latent arteriosclerosis (von Basch), essential hypertonia (Frank), and "prealbuminuric stage" of chronic Bright's disease (Mahomed).

Apart from long use and wide acceptance, the term "essential hypertension" has little to recommend it. it is unscientific and far from ideal. The term "primary hypertension" is more informative, in that it indicates the absence of *demonstrable causes*.

Historical Landmarks. The oldest reference to hypertension is accredited by Volhard to the ancient Chinese physician Choun-You (200 B.C.), according to whom a pulse that feels "very firm" on depressing and "very tight" on superficial feeling should suggest kidney disease, an observation that cannot be bettered today after centuries of scientific progress.

The first measurement of arterial blood pressure by the direct method was made by Stephen Hales (1733), who, out of curiosity, introduced a long tube into the femoral artery of a mare and observed pulsations of the ascending column of blood within the tube.

Richard Bright of London commented on the increased resistance to injection offered by arterial vessels in renal diseases (1827). After an exhaustive study of renal disease, he could find no possible cause for the cardiac hypertrophy which he noted in 22 out of 52 cases. One of the two explanations suggested by Bright for the hypertrophy was a change in "the minute and capillary circulation as to render greater action necessary to force the blood through the distant subdivisions of the vascular system"; in other words, increased peripheral resistance and hypertension. The role of hypertension as the connecting link between Bright's

become normal after medical treatment of hypertension.

The general correlation between high blood pressure and the 24-hr output of urinary sodium tends to persist even after lowering of the arterial pressure by medical or surgical means (Green and Ellis, 1954). Whether the natriuresis of hypertension is primary and conducive to the development of hypertension or is secondary to the renal involvement of hypertensive disease remains conjectural (Cottier et al, 1958).

The distribution of sodium in the body is perhaps of greater etiologic significance in hypertension than the total amount of sodium in the body. Abnormally high amounts of sodium have been demonstrated within the arterial walls, renal arteries, and psoas muscles of hypertensive persons, even the sodium content of the blood serum and cerebrospinal fluid is higher than normal in such cases (Edwards, 1960).

The relation of salt intake to high blood pressure has also been fully investigated by several workers, with conflicting results. In one series of cases, hypertension was nonexistent in individuals on low salt intakes while it was present in all persons with high sodium intake. Moderate rises of systolic and diastolic pressure have been reported in normotensive persons after the ingestion of 25 to 60 Gm salt (McDonough and Wilhelmi, 1954). A high salt intake has been considered as a cause of hypertension in tropical climates (Schroeder, 1958). Restriction of salt to below 1 Gm/day or of sodium ion to below 200 mg/day may bring about return of blood pressure levels to normal in about 30 per cent of hypertensive patients (Martini and Kaiser, 1954).

According to Freis (1960), salt plays a secondary rather than a primary role in hypertension. Whether disturbance of the salt metabolism is primary and conducive to hypertension or secondary to the renal effects of hypertension, whether a high salt intake is essential for the development of hypertension, and whether salt restriction is indicated routinely in the treatment of high blood pressure are only some of the many unsolved questions of the day, regarding the role of salt in hypertension

Clinical Manifestations ONSET In the great majority of patients with essential hypertension, the disease is discovered either accidentally or during a routine clinical or insurance examination, the condition then being more or less asymptomatic. In some persons, the onset is insidious or gradual, with a few occasional symptoms suggestive of hypertension, such as *headache*, *giddiness*, and *palpitation*. In some, the disease is discovered because of one or another of its possible complications, such as renal or cardiac insufficiency. In a few cases, its manifestation is acute, as in cerebral hemorrhage or thrombosis or myocardial infarction.

CLINICAL PICTURE. The clinical picture of hypertension is variable and heterogeneous, depending on the degree, type, and persistence of the high pressure, the organ or organs preponderately affected, and the patient's own reaction or behavior toward the illness.

Essential hypertension is compatible with a normal and asymptomatic existence for years, the patient remaining completely unaware of its presence In such cases, the onset of symptoms may coincide with the disclosure of the diagnosis to the patient. Certain *premonitory symptoms*, such as migraine headache, repeated nosebleeds, and irritability, are at times experienced by the patient many years before the discovery of the disease proper. Many investigators have felt that essential hypertension is asymptomatic and that most of the symptoms that appear to be produced by it are actually due to iatrogenic or psychoneurotic factors, later complications of the disease, or coincidence with other diseases.

The most common symptoms encountered in essential hypertension may be conveniently grouped into premonitory hypertensive, atherosclerotic, cardiac, renal, neurogenic, psychoneurotic, iatrogenic, and coincidental symptoms

SYMPTOMS. The early symptoms of hypertension include headache, dizziness, vertigo, precordial ache or "fullness," palpitation, excessive fatigue, lassitude, nocturia, polyuria, tightness of scalp, pain in the back of the neck, irritability, blurring of vision, insomnia, tinnitus, emotional instability, dry cough, and lack of concentration In other cases, attention may first be drawn to the ailment because of epistaxis, episodes of coronary thrombosis, cerebrovascular episodes, paroxysmal dyspnea, sudden blindness, mental impairment, vomiting, muscle twitching, generalized convulsions, intermittent claudication, vasomotor phenomena including "dead fingers," joint pains, pares- [illegible] ... tite. The clinical pic-

4. Metabolic
   a. Overeating
   b. Deranged metabolism of proteins, carbohydrates, fats, salt, or purines
5. Neurogenic
   a. Organic lesions of central nervous system
   b. Lesions of autonomic nervous system
6. Psychogenic (psychosomatic)
7. General adaptation syndrome—intensification, protraction, or perversion of the "adaptation syndrome," a protective mechanism against "stresses" such as fatigue, cold, infection, emotion, and intoxication (Selye)
8. Miscellaneous—intestinal disturbances, infection, syphilis, allergy, abuse of tobacco, lead poisoning

There are two ways in which pressor substances may conceivably increase arteriolar tone: (1) normal vascular reaction to excessive amounts of vasoconstrictor or pressor substance, (2) excessive vascular reaction to normal amounts of pressor substance

ETIOLOGIC FACTORS Evidence at hand suggests the participation of several important factors, besides the so-called pressor mechanism, in the genesis of essential hypertension (1) hereditary or genetic factor, (2) constitutional factor, (3) environmental factors, (4) intrinsic sensitization of target organs (the arteriole)

Genetic Factor. An inherited tendency to hypertension is suggested by several studies The familial incidence, studies in twins, and proved inheritance of vascular hyperreactivity to the cold-pressor test (Hines, 1937), support such a theory The predisposition to the disease is probably inherited as a mendelian dominant characteristic (Weitz). According to Ayman (1934), the likelihood of occurrence of hypertension in the offspring is about 3 per cent with normotensive parents, 28 per cent with one parent hypertensive, and 46 per cent with both parents hypertensive

Constitutional Factor The constitutional make-up of the hypertensive male, inclusive of physical, emotional, and mental characteristics, is somewhat typical. He is usually a broad, stockily or squarely built, hypersthenic person of mesomorphic type, emotionally dynamic, ambitious, and aggressive Weiss and Parker (1939), after a somatometric study of 3,000 persons selected at random, were able to demonstrate an unequivocal relationship between blood pressure and thoracic circumference; a lesser degree of correlation was observed between the "height-weight ratio" and blood pressure, the former being inversely proportional to the latter.

Psychopathology. Many workers have been impressed by the association with hypertension of certain personality patterns or traits. The most important of these is an aggressive or explosive temperament, a conflict between hostile impulses and dependent needs, and a tendency to worry over trifles. According to Menninger (1938), beneath a deceptively gentle façade, the hypertensive individual displays a strong undercurrent of fear or hostility based on a threat to his security.[2] Many other investigators have cast doubt on the accuracy or validity of any simple personality profile for hypertension.

Environmental Factors. Dietary factors (overeating), excess of fats or calories in the diet, and emotional traumatic experience may also be important predisposing factors.

The Role of Salt in Hypertension. The role of electrolytes, and particularly of salt or sodium chloride, in the genesis of hypertension has been the subject of considerable debate in recent years Despite innumerable investigations, there is as yet no unanimity of opinion on the subject.

Patients with essential hypertension show augmented urinary salt excretion both in basal condition and under salt load, e.g., after infusion of saline solution and water In comparison with normotensive subjects, hypertensive persons appear to retain sodium and water more readily on a sodium-free diet and excrete more sodium and water under salt load (Hollander and Judson, 1958). On the basis of salt excretion in hypertensive patients, Green and Ellis (1954) recognized two groups of hypertensive persons (1) high salt excreters, probably in the early phase of hypertension, and (2) normal salt excreters, probably in advanced stages of hypertensive disease. Cyclic derangements of sodium chloride exchange and excretion of similar nature were demonstrated in human subjects with hypertension and in animals with experimental hypertension (Wilson, 1953, Taquini, Blaquer, and Taquini, Jr., 1958, Birchall et al., 1953). The increased sodium excretion, or natriuresis, of hypertensive patients under salt load appears to depend not on renal factors (such as impaired tubular resorption of sodium), increased adrenal activity, or modifications of osmotic pressure, but rather on some extrarenal mechanism (Baldwin et al., 1958, Selkurt, 1951; Chinard, 1958). The high excretion of sodium under load is probably related to the level of the raised arterial blood pressure (Hollander and Judson, 1954), and tends to

Benign and Malignant Phases. The recognition of a *severe or malignant form of essential hypertension* in younger age groups, with acute and rapidly progressive renal insufficiency leading to renal failure, high diastolic pressure, and typical lesions (endarteritis, arteriolar necrosis, and multiple thromboses of small renal arteries), was made possible by Volhard and Fahr (1914). The slowly progressive benign and much more common form of essential *hypertension*, accounting for about 90 per cent of cases, is associated with little or no evidence of renal insufficiency, and was described by Volhard and Fahr as *benign hypertension*

Keith, Wagener, and Kernohan (1928) later presented a classic description of the "syndrome of malignant hypertension" based on the study of 81 cases. After this description it became customary to regard benign and malignant hypertension as clinically *distinct* entities, with different rates of progression, and different incidence of renal involvement, clinical and pathologic manifestations, and prognosis Such a viewpoint cannot be maintained, for several reasons Malignant hypertension may arise at any time during the *course* of an apparently benign or asymptomatic *form of* hypertension, and may even rarely revert to the benign form, either because of treatment or naturally. Benign and malignant *forms of* hypertension may be encountered at *times in* different members of the same family. The pathologic lesion of arteriolosclerosis is common to both the benign and the malignant forms of the disease It is, therefore, imperative to regard the two syndromes as phases of the same disease, rather than as *distinct* clinical entities. In view of the dreadful implication of the word "malignant" to the patient and ...

... ...

The mechanism of the malignant phase remains obscure, in spite of numerous clinicopathologic studies According to many investigators the basic difference between "malignant" and "benign" hypertension is one of *degree* only, the former being no more than an aggravation or acceleration of the disease process, *secondary to persistent and excessive elevation of diastolic pressure*. In conclusion, depending upon the rate of progression of the disease, two main phases of essential hypertension may be recognized.

1 *Benign (nonmalignant or chronic) phase*. This is usually characterized by gradual or insidious onset, long duration extending over 10 to 40 years, slow progression, little or no evidence of renal insufficiency, diastolic level usually below 125 mm Hg, hypertensive retinopathy of grade I, II, or III, and normal blood chemistry. The prognosis is relatively good

2. *Malignant (accelerated, papilledematous, or acute) phase*. This is characterized by acute or subacute onset, rapid *progression, short* course (under 2 years), diastolic level usually over 125 mm Hg (at times 150 *or more*), retinopathy of grade IV with papilledema (*at times, grade III type of fundus*), *early* evidence of azotemia, and renal failure. The kidney has a poor concentrating power, with albuminuria and microscopic hematuria. Present also are anemia, nausea and vomiting, severe headaches, *often convulsions*, rapid and progressive *loss of* vision, tendency to involuntary muscle movements The prognosis is grave, *and early death* may be expected This prognosis may now be modified by treatment. At times, differential diagnosis between the two forms of hypertension is extremely difficult, particularly when grade III retinopathy is associated with evidences of renal dysfunction

Cardiovascular Manifestations. In essential *hypertension*, two major factors act on the heart: (1) *mechanical overload*, due to the increased peripheral resistance (arteriolar vasoconstriction); (2) *inadequate blood supply* (myocardial ischemia), due partly to coronary atherosclerosis and partly to relative ischemia of the hypertrophied myocardial fibers. In hypertensive hypertrophy of the heart, the muscle fibers increase in size but not in number, the fiber-capillary ratio remaining unchanged, the capillaries being *unable* to cope with the demands, there is decreased exchange of oxygen and metabolites. In spite of these influences, the heart is able to carry on, as a rule, for ... of its compensatory

ture of hypertension is greatly influenced by the site, degree, and nature of atherosclerotic complications, the presenting symptom or symptoms being therefore of cardiac, coronary, aortic, arterial, renal, cerebral, musculoskeletal, or ocular origin

Headache. Headache is encountered in the great majority of cases of hypertension, particularly in malignant hypertension. It is recurrent, frequently occipital, tends to occur in the early hours of the morning, and is not necessarily related to the degree, duration, or type of hypertension Headache is relieved at times by sitting up, standing, and moving about; it is frequently improved by hypotensive drugs, is associated in some cases with nausea or vomiting, and is often accompanied by tightness or aching of the neck muscles Usually due to the raised level of arterial pressure, particularly diastolic, the headache of hypertension may also be caused by complication of the hypertension, raised intracranial tension, renal insufficiency, encephalopathy, cerebrovascular lesion, tonic spasm of head and neck muscles (Wolff, 1948), psychogenic or iatrogenic factors, dilatation of carotid artery branches (Wolff, 1948), or true migraine

Dizziness and Vertigo A sudden feeling of unsteadiness or insecurity, or true vertigo, may occur from time to time in essential hypertension, particularly in association with a sudden change of posture or when the patient is taking ganglion-blocking drugs It is usually due to vascular disturbances of the internal ear or eighth nerve Of similar origin are buzzing, ringing, or "sea-shell" noises (*tinnitus*), this complaint, though usually transitory, is often refractory to treatment

Recurrent hemorrhages of varying severity (epistaxis, menorrhagia, metrorrhagia, hematuria, or subjunctival or retinal hemorrhages) may commonly occur in hypertension

PHYSICAL SIGNS The only signs which can be directly attributed to the hypertension are the hard pulse, the abnormal 2d sound in the aortic area, and the *forceful or heaving apex beat*. First described by Traube (1870), the hard pulse of hypertension is like a "taut iron wire," difficult to compress but not necessarily increased in volume or amplitude The loud aortic 2d sound of hypertension, also described by Traube, is frequently associated with a palpable shock or thud and a ringing or metallic quality. Usually attributed to forceful closure of the aortic valve, this sign has some diagnostic value. Unfortunately, it is also present in syphilitic aortitis, aortic atheromatosis, and aneuryism of the aorta. Moreover, the typical aortic 2d sound may be absent if there is associated pulmonary emphysema or obesity. A heaving apex beat, even when normally located, must suggest the possibility of left ventricular hypertrophy secondary to hypertension.

COMPLICATED HYPERTENSION

Essential hypertension, in its early stage, with few or no clinical manifestations, is usually referred to as *uncomplicated* hypertension When clinical symptoms and signs, suggestive of cardiac, aortic, renal, cerebral, or retinal involvement, are present, the hypertension is described as complicated.

COMPLICATIONS OF HYPERTENSION

I Cardiac involvement—left ventricular hypertrophy (compensated phase)
  A Cardiac failure (decompensated phase)
    1 Left ventricular failure
    2 Combined failure
  B Coronary insufficiency
    1 Myocardial infarction
    2 Angina pectoris
    3 Intermediate coronary syndromes
    4 Sudden death
II Aortic involvement
  A Atheroma of aorta
  B Aortic aneurysm
  C Dissecting aneurysm
  D Thrombotic occlusion
III Involvement of peripheral arteries
  A Peripheral arteriosclerosis
  B Peripheral gangrene
  C Thrombotic occlusion
IV Cerebral involvement
  A Hypertensive encephalopathy (spasm or edema)
  B Cerebral thrombosis
  C Cerebral hemorrhage
  D Subarachnoid hemorrhage
  E Cerebral atherosclerosis
  F Cerebrovascular insufficiency
V Renal involvement
  A Benign nephrosclerosis
  B Malignant nephrosclerosis
  C. Functional disturbances
VI Involvement of eyes
  A Hypertensive retinopathy
    1. Grade I—vascular spasm
    2 Grade II—vascular sclerosis
    3 Grade III—exudative phenomena (hemorrhages, exudates, and edema)
    4 Grade IV—papilledema

starting days or weeks before the initial episodes of paroxysmal dyspnea.

The physical signs, although striking and constant in such cases, are often missed. The most important is a triple rhythm (older term, "gallop rhythm"), which is most often presystolic but may be protodiastolic or of the summation type. This is best heard near the apex, and is due to the presence of an extra sound during diastole. Once considered of ominous significance and pathognomonic of left ventricular failure, triple rhythm is compatible with fairly long survival, may persist in spite of additional right ventricular failure, and may disappear with therapy.[4] The other signs of left ventricular failure are an outward and downward displacement of the apex beat (at times, in the anterior axillary line, in the 6th and left interspace), with increased amplitude and extent but relative decrease of force (less forceful than during the previous stage of left ventricular hypertrophy), indicating dilatation of the left ventricle, increased loudness of the 2d sound over the pulmonary area (the pulmonary 2d sound becomes as loud as the aortic sound or even louder); moist rales over the lung bases (at times throughout both lungs), pulsus alternans (with regular alternation of strong and weak beats at the radial pulse), best appreciated with a sphygmanometer (Gallavardin's sign), a sudden doubling of the sounds being detectable during deflation of the cuff.[4]

Combined Failure Insufficiency of both ventricles (left- plus right-sided failure) may occur in hypertension, usually after a phase of left ventricular failure of varying duration, provided the patient has not already succumbed to other major complications, such as coronary thrombosis, renal failure, or cerebral hemorrhage.

The onset of right ventricular failure is usually manifested by *signs of systemic venous stasis*, including dependent edema (usually at the ankles or pretibial in ambulatory cases and sacral in recumbent cases), hepatomegaly, and engorgement of the cervical veins. Evidence of enlargement of the heart to the right and left, and transudates in the serous cavities (hydrothorax or ascites) become apparent. *Ectopic rhythms* are common (premature beats, atrial fibrillation). It is interesting that occasionally even when cyanosis develops, paradoxical improvement in the severity of dyspnea occurs (tricuspid insufficiency). In severe cases, and particularly in elderly subjects, *periodic respiration* of the Cheyne-Stokes type, a soft, early diastolic aortic murmur, restlessness, and delirium may further complicate the picture.

X-ray may disclose a huge heart, of a triangular or globular cardiac configuration, with diminished pulsations. The *electrocardiogram* may show low voltage, sinus tachycardia, various types of arrhythmias, and evidence of both right and left strain, with or without evidences of hypertrophy.

Bernheim's Syndrome. In a few cases of hypertension with left ventricular enlargement, the clinical picture may be dominated, paradoxically enough, by right ventricular, rather than left ventricular, failure. Evidence of systemic venous stasis may predominate over that of pulmonary congestion. This syndrome was described by Bernheim (1910) and attributed to massive hypertrophy and rigidity of the interventricular septum, reducing right ventricular filling. However, the very existence of this syndrome is denied by several contemporary authors.[5]

Coronary Thrombosis In some patients with hypertension, the clinical picture may be dominated or initiated by myocardial infarction.

Exertional Precordial Pain (Angina of Effort). In many cases of hypertension, with or without evidences of ventricular hypertrophy or strain, precordial pain may disturb the patient long before the advent of dyspnea. Typically paroxysmal and related to physical exertion, excitement, or overeating, the pain or sensation of constriction starts retrosternally, usually radiates to the left arm (at times, down the right arm or both arms, or to the left elbow, lower jaw, epigastrium, or back), attains its peak within a matter of seconds or minutes, lasts usually for 1 to 20 min, and usually responds promptly to rest or nitrites. Transient depressions of the S-T segment, with diphasic or inverted T wave in several leads

[4] The description and significance of triple rhythms, as well as alternans, may be found in Part 5, Chap 4. *Editor*.

[5] Recent reports have shown the possibility of either pulmonic or aortic stenosis as a result of hypertrophy of the ventricular septum. On the other hand, no single case of Bernheim's syndrome has been confirmed, so far, by catheterization. *Editor*.

mechanisms, and the patient remains asymptomatic. In some cases, however, cardiac manifestations appear early, dominating the clinical picture.

CARDIAC MANIFESTATIONS The heart may be affected in the following ways:

I. Left ventricular hypertrophy (compensated heart)
II. Cardiac failure
   A. Left ventricular failure
   B. Combined (left and right) failure
   C. Bernheim's syndrome (or paradoxical failure)
III. Coronary insufficiency
   A. Coronary thrombosis (followed by myocardial infarction)
   B. Exertional precordial pain (older term, "angina of effort")
   C. Intermediate coronary syndrome
   D. Sudden death
IV. Terminal pericarditis (final stage of malignant hypertension)—very rare
V. Valvular involvement—rare

Left Ventricular Hypertrophy The earliest and commonest effect of hypertension on the heart is hypertrophy of the left ventricle. It is the result of the increased work of the heart against the increased peripheral resistance. It is completely asymptomatic.

This ventricular hypertrophy is usually accompanied by little or no dilatation (concentric hypertrophy). Therefore, the size of the heart may appear normal on physical examination; the apical thrust is either in its normal place or is but slightly displaced downwards and (at times) outwards. The most dependable sign of left ventricular hypertrophy is a forceful or heaving apex beat, that lifts the palpating finger with force; the amplitude of apical pulsation is usually normal, unless there is cardiac dilatation or thyrotoxicosis. There may be increased retromanubrial cardiac dullness on percussion, a loud, booming, prolonged (and at times split) 1st heart sound at the apex, a loud, sharp, and metallic 2d sound at the aortic area, a systolic apical murmur (caused by dilatation of the AV ring or mitral valvular sclerosis), a systolic murmur at the aortic area (caused by dilatation of the aorta or a sclerotic aortic valve), and, at times, a characteristic, frequently transitory, diastolic murmur (due to functional aortic regurgitation) over the basal areas of the heart.

X-ray may reveal a boot-shaped, transversely placed cardiac silhouette, with increased convexity of the left lower border (best seen during deep inspiration), and a rounded or blunt apex; the transverse diameter of the heart may be normal.

The most common and important *electrocardiographic findings* are left axis deviation, increased voltage of the QRS complex (large S waves in V_1 and V_2 and large R waves in V_5 to V_6), increased duration of the QRS complex (over 0.11 sec), depression of the S-T segment (over 0.5 mm), and inversion or depression of the T wave in lead I (at times also in lead II), AVL, V_5 *to* V_6. $R_1 + S_3$ is usually over 20 mm, and $SV_1 + RV_5$ or V_6 is over 28 mm. The characteristic S-T and T-wave changes of leads I and II have been variously attributed to ischemia of the left ventricle, change in position of the heart, and rotation of the heart caused by left ventricular hypertrophy.

After a variable period of time (weeks to years) the compensatory phase of left ventricular hypertrophy may change to isolated *failure of the left ventricle* (Gallavardin). The development of failure may be insidious or acute, and triggered by a variety of factors, such as myocardial ischemia, acute respiratory infection, sudden rise of blood pressure caused by excitement, anger, exposure to cold, severe exertion, nightmares, emphysema, or a valvular lesion.

Left Ventricular Failure The presenting symptom in most cases of early left heart failure is *dyspnea*. This may be acute and nocturnal (paroxysmal nocturnal dyspnea; older term—"cardiac asthma"), arising suddenly in the early hours of the night, with air hunger, orthopnea, restlessness, and cough. It may also develop more gradually, as exertional dyspnea. In more advanced cases, the dyspnea may become continuous. Paroxysmal nocturnal dyspnea may be complicated by acute pulmonary edema, with expectoration of pink, frothy sputum.[3] The intensity, duration, nature, and frequency of such attacks vary from patient to patient. Careful questioning may elicit a history of prodromal or premonitory symptoms of dry nocturnal cough, nocturia, oliguria, insomnia, exertional fatigue or dyspnea, and decreasing exercise tolerance,

[3] Paroxysmal pulmonary edema is discussed in detail in Part 18. *Editor.*

retinal vessels, retina, and optic disk, and presents a wide variety of ophthalmoscopic appearances

The classificaton of hypertensive retinopathy into [illegible] grades or degrees of increasing severity, [illegible] forward [illegible] states [illegible] tic and prognostic importance regarding hypertension.

Grade I (vascular spasm): narrowing of smaller arterioles with localized constrictions and increased tortuosity

Grade II (vascular sclerosis): narrowing of arteries, with irregular, waistlike constrictions and increased tortuosity, exaggeration of "light reflex" through thickening of arterial walls, "copper wire" appearance of arteries when filled with blood, and "silver wire" appearance when relatively empty, full veins or distended and tortuous ones; altered "artery to vein diameter ratio", arteriovenous compressions (Gunn's phenomenon), resulting in nicking of veins, invisibility of underlying veins, and *U-shaped or S-shaped venous curvatures*

Grade III (hypertensive neuroretinitis or exudative retinitis), same as grade II, but with additional features, soft, "cotton-wool exudates" or patches with fluffy margins, multiple or single flame-shaped or striate hemorrhages, retinal edema, with haziness of outlines of retinal vessels and (occasionally) blurring of disk margin

Grade IV (papilledematous retinitis) same as grade III, but with additional features papilledema, with the optic disk clearly raised above the level of the retina and shallowness or absence of the physiologic cup Grade IV retinitis is usually considered diagnostic of the malignant phase of hypertension

In Leatham's opinion, a presumptive diagnosis of hypertension is justified in the presence of one or more of the following ophthalmoscopic criteria (1) irregularity of lumen of two or more arterioles; (2) generalized narrowing of arterioles, with arteriole-venule diameter ratio of 1:2, and (3) arteriovenous nicking, pallor of arteriolar column, and broad or bright "light streaking."

NATURAL HISTORY OF HYPERTENSION

Increasing familiarity with the disease suggests that evolution or development of hypertension is a long process, probably beginning at birth with a predisposition to the disease and developing, stage by stage, as outlined below

1. Hereditary (constitutional or familial) tendency (potential hypertension)
2. Prehypertensive phase (latent hypertension)
3. Intermittent (phasic, episodic, or neurogenic) hypertension
4. Established (sustained, persistent, or continuous) hypertension, uncomplicated
5. Established hypertension, complicated–associated with cardiovascular, renal, cerebral, or other complications, or with the malignant syndrome
6. Death (from cardiovascular, cerebrovascular, renal, or coincidental causes)

Prehypertensive Phase. This may be detectable years before the actual onset of high blood pressure, by observation of the following features: (1) high levels of blood pressure during states of mental strain, e g , during insurance examination; (2) occasional pressure readings in the upper ranges of normal or well above average or mean levels, (3) hyperreaction or increased reactivity to pressor stimuli. The latter may be of the nature of reflex stimulation, e g , cold-pressor test (Hines and Brown, 1935), muscle ischemia test (Alam and Smirk, 1938), or Valsalva maneuver (Finnerty and Freis, 1950); chemical stimulation, e g., carbon dioxide inhalation (Raab, 1953) or breath-holding test (Ayman and Goldshine, 1939); pharmacologic stimulation (after blocking the control mechanism with hexamethonium) with norepinephrine, angiotension, or S-methyl-iso-thiourea (Doyle and Black, 1955); or psychic stimulation, e.g., emotional stimulation through tense interview or mental tension.

Of the various tests for vascular responsiveness or reactivity, the most useful is the *cold-pressor test* After the basal pressure level has been determined, the patient's hand is immersed in ice-cold water up to the wrist for 1 min. The blood pressure is measured in the opposite arm, every ½ min for 1 min and, later, every 2 min, until the basal level is regained. A pressure reaction below 20/15 is called "normal hyporeaction", over 20/15, "normal hyperreaction"; and over 30/20 or 40/30, "abnormal hyperreaction," suggesting hypertension in its prehypertensive or latent phase.

Intermittent Hypertension. In the functional or spastic stage of hypertension, elevations of blood pressure are usually phasic or episodal, lasting for minutes, hours, or days and alternating with phases of normotension. Detection of hypertension in this stage is important, because of a good response to treatment.

of the electrocardiogram, are common during an attack of pain, although the electrocardiogram may be completely normal between attacks. Angina pectoris in a hypertensive patient, as in a normotensive patient, may be frequently associated with a transitory rise in blood pressure. Precordial pain of hypertension does not always indicate coronary atherosclerosis, since typical pain may be due to inadequate blood supply (coronary insufficiency) resulting from myocardial hypertrophy and increased cardiac work. However, moderate coronary arteriosclerosis is usually present.

Intermediate Coronary Syndrome. Clinically intermediate between angina pectoris and coronary occlusion is a coronary syndrome, neglected in the past, that has been variously designated as coronary failure (Blumgart et al., 1941), acute coronary insufficiency (Master et al., 1947), intermediate coronary syndrome (Graybiel, Vakil), and prethrombotic syndrome (Vakil, 1951). The pain is then typically retrosternal but lasts for hours instead of minutes, and is not associated with fever, leucocytosis, high sedimentation rate, and increase of transaminase, as in myocardial infarction.

Valvular Lesions. Involvement of the mitral or aortic valves may, at times, complicate the clinical picture of hypertension. The cause of the lesion may be rheumatic, syphilitic, or atherosclerotic. *Calcific aortic stenosis* is probably the more common coexisting lesion. The differentiation between obstructing aortic stenosis, nonobstructing aortic stenosis, and relative aortic stenosis must then be made.

Arterial Manifestations. Besides involving the small arterial vessels supplying blood to vital organs, such as the heart, kidneys, and brain, hypertension may also affect the aorta and the peripheral arteries of the extremities.

Aortic involvement, in hypertension, usually consists of atherosclerosis, causing elongation and dilatation of the aorta. Usually symptomless, except in cases of massive aneurysm or embolization, aortic involvement may be suspected on the basis of certain physical signs: visible and palpable pulsation of the aortic arch, above and behind the manubrium, visible and palpable arterial pulsation in the right lower cervical region (Rowntree's sign), dullness over the manubrium, loud and ringing 2d sound, moderately loud systolic murmur at the aortic area, and a high pulse pressure.

Cerebral Manifestations. Apart from nonspecific symptoms, such as headaches, fatigue, throbbing sensations, and vertigo, certain characteristic symptoms may suggest cerebral involvement. The following *cerebral syndromes* may occur:

I Hypertensive encephalopathy
  A Vasospasm with cerebral hypoxia
  B Cerebral edema
  C. Minute vascular accidents
II Cerebrovascular accidents
  A Cerebral thrombosis
  B Cerebral hemorrhage
III Cerebral atherosclerosis
  A Atherosclerotic Parkinsonism
  B Pseudobulbar palsy
  C Mental degeneration
IV Cerebral symptoms of uremic origin

HYPERTENSIVE ENCEPHALOPATHY. Attacks of hypertensive encephalopathy were described for the first time by Fishberg (1928). Usually transitory, these attacks, caused by cerebral angiospasm, may result in a variety of disturbances of cerebral function: sudden and transitory loss of consciousness, aphasia, convulsions, paresis or paralysis, sensory disturbances, amaurosis, and disorientation. Particularly frequent during the malignant phase of hypertension, these evanescent episodes may be due to cerebral hypoxia, cerebral edema (secondary to vasoconstriction), or minute thrombosis involving silent areas of the brain. A sudden and severe drop of blood pressure, secondary to ganglion-blocking agents, may be responsible for hypoxia if certain cerebral vessels are rigid and narrow.

Hypertensive Retinopathy. Observed ophthalmoscopically, for the first time by Heymann (1856), and lucidly described under the designation of *albuminuric retinitis* by Liebreich, the retinal manifestations of hypertension include three main types of retinopathy: hypertensive, arteriosclerotic, and diabetic.

The characteristic retinopathy of hypertension (hypertensive retinopathy), which is common to most forms of hypertension and is frequently associated with a high level of diastolic blood pressure (as in malignant hypertension), involves, to a variable extent, the

in the literature of the past. In spite of possible serious complications, such as congestive failure and cerebral hemorrhage, which may kill some patients and cripple others, the average life span of an untreated hypertensive patient is about 20 years, with a wide range of from several hours to over 40 years. Essential hypertension frequently proves fatal during the fifth decade of life, and reduces the life span by about 10 years (Weitz and Fishberg) Depending on the method of selection of cases and on the nature of the survey employed, the prognosis of hypertension has been outlined in different manner by different observers.

Benign essential hypertension is, as a rule, a slowly progressive disease, compatible with many years of comparatively comfortable existence. In Riseman's opinion, it is "not conducive to longevity but is compatible with longevity."

Causes of Death. The major causes of death and invalidism in hypertension are congestive failure (50 per cent), coronary heart disease (15 per cent), cerebrovascular accidents (15 per cent), uremia (8 per cent), and coincidental or unrelated ailments (12 per cent). Two-thirds of all deaths are due to involvement of the heart or its arteries.

Cure or Recovery. A genuine cure or disappearance of high blood pressure is seldom, if ever, possible in an established case of essential hypertension. A transitory or persistent drop of pressure to normal may, however, occur through a complication, such as coronary thrombosis, peripheral failure, or shock (as in peritonitis or following a cerebrovascular attack; through general debility, malnutrition, or cachexia, or as the result of medical or surgical treatment. A genuine recovery also appears possible during the earlier prehypertensive and intermittent phases of essential hypertension, when the functional vascular disturbance is apparently still reversible.

Data of Prognostic Significance. The complications and sequelae that may result from essential hypertension or its major complication, atherosclerosis, are many Prognosis is therefore extremely difficult. Data on the following topics are of some prognostic value and must therefore be carefully evaluated in all cases.

AGE. The outlook is, as a rule, better in elderly persons than in the young. The incidence of malignant hypertension is higher in younger age groups.

SEX. Because of the lower incidence of coronary disease and malignant hypertension in women, the outlook is better in women than in men, death expectancy being only about half that of males.

LEVEL OF BLOOD PRESSURE. The outlook depends, to some extent, on the degree of elevation of diastolic and systolic pressures, particularly the former. For this purpose, basal readings of pressure are far more dependable than casual. The mortality rate and incidence of complications increase proportionally with the increase of blood pressure up to about 210/120, above this level, there is a steep rise, mainly because of the high incidence of cerebral hemorrhage and malignant hypertension.

FIXITY OF BLOOD PRESSURE. The prognosis is better in the labile form of hypertension, even if the pressure level is high, than in the fixed or refractory form. The former type is also more amenable to therapeutic measures

TYPE OF HYPERTENSION. Diastolic hypertension, as a rule, is far more serious than systolic hypertension, which may be the result of aortic atherosclerosis.

SYMPTOMS. The mortality rate of hypertensive patients presenting symptoms is about five times that of persons with latent or asymptomatic hypertension (Frant and Coren, 1950).

RETINAL GRADING According to Wagener and Keith (1939), the 5-year mortality rate of hypertensive patients is 30 per cent for grade I, 40 per cent for grade II, 80 per cent for grade III, and 99 per cent for grade IV, the average duration of life for those with the malignant or papilledematous form of hypertension being only about 1 year. True papilledema is therefore a sign of ominous significance.

OBESITY. Excessive body weight tends to increase the mortality rate in hypertension by predisposing to coronary heart disease.

RENAL FUNCTION. Impaired concentrating ability of the kidney and high nitrogen retention in the blood indicate a bad prognosis, unless accounted for by prerenal azotemia or prostatic obstruction. Among urinary abnormalities, massive albuminuria and excess of granular casts are particularly significant and often indicate a poor outlook

DIAGNOSIS

Diagnosis of essential hypertension implies the demonstration of persistently elevated diastolic and systolic blood pressure levels, in the absence of all known causes of hypertension, such as renal, endocrine, and cerebral disease.

Diagnostic difficulties may arise in cases of early, borderline, intermittent, or latent hypertension. Occasionally high blood pressure, particularly during medical, insurance, or military examinations or under conditions of sustained emotional stress (e.g., during combat duty or states of psychosis), may be either an evanescent phenomenon of no significance or a sign premonitory of true hypertension. Serial observations of basal blood pressure readings may prove necessary in such cases for establishing the final diagnosis.

The blood pressure, even in severe hypertension, may drop to normal after a major complication, such as myocardial infarction or cerebral thrombosis The hypertensive disease may then be missed unless it was known to have been present prior to the catastrophic illness A persistently high level of the diastolic pressure, in spite of a drop of mean pressure, may reveal the preexisting condition.

Differential diagnosis of malignant from benign hypertension may prove difficult when advanced retinal changes, urinary abnormalities, or very high levels of blood pressure are present. Mere blurring of the margins of the optic disk, through retinal edema, as in grade III hypertension, may be mistaken for true papilledema, while the finding of albumin and casts in the urine may prejudice the examiner in favor of the malignant syndrome

Systolic hypertension, from coarctation of the aorta, senile atheromatosis, or thyrotoxicosis, may be incorrectly diagnosed and the patient may be treated for essential hypertension if no attention is paid to the level of diastolic pressure.

Since success or failure of treatment depends to a great extent on a correct appraisal of the nature and type of the high blood pressure state, a systematic method of interrogation and investigation, such as the following, is essential in every case of suspected hypertension.

I. Interrogation
   - *A.* Routine: familial incidence, age, sex, occupation
   - *B.* Special: onset; duration; progress, aggravating and relieving factors; associated symptoms; presence of complications

II. Routine examination
   - *A.* Blood pressure: brachial pressure (right and left sides); postural effects (pressure readings in recumbent, sitting, and standing postures), femoral pressure; pulse pressure; basal and supplemental pressures; Gallavardin's sign (detection of pulsus alternans by sphygmomanometry).
   - *B.* Pulse: rate, rhythm, force, tension, appearance, character, inequality, condition of the arterial wall; pulsus alternans.
   - *C.* Routine system review (particularly cardiovascular system). Special attention should be paid to the following: apex thrust (site, intensity, character, extent); pulsatory phenomena at the base of the heart; heart sounds (comparative intensity of aortic and pulmonary 2d sounds), triple rhythm; rales and rhonchi; edema; cyanosis; hepatomegaly; serous effusions, Rowntree's sign (pulsation in right lower cervical region).

III. Routine investigations
   - *A.* Blood tests: routine blood count; erythrocyte sedimentation rate, serologic tests, blood urea and nonprotein nitrogen; fasting blood sugar; blood cholesterol, serum sodium, potassium, and chloride; carbon dioxide combining power.
   - *B* Urine tests. protein (albumin); specific gravity, sugar; sediment (cells, casts, red blood cells, etc.); color; polyuria, oliguria, nocturia, phenol sulfonephthalein test
   - *C* Electrocardiogram: axis deviation, voltage and duration of QRS complex, T-wave flattening or inversion, S-T changes; other abnormalities.
   - *D.* Fluoroscopy size of cardiac silhouette; border convexity of left ventricle, pulsations, aorta, hilar shadows; lung fields, fluoroscopy in RAO and LAO positions, skiagrams of chest, roentgenograms of abdomen, intravenous pyelography; x-rays after perirenal insufflation.

IV Special investigations
   - *A* For essential hypertension. circulation time (arm-to-tongue time; arm-to-lung time), cold-pressor and other pressor tests, sedation test (Amytal)
   - *B* For secondary forms of hypertension (discussed below).

PROGNOSIS

The prognosis of the average case of essential hypertension is not so gloomy as portrayed

- III. Neurogenic
  - *A* Cerebral
    1. Raised intracranial pressure
    2. Fracture of the skull
    3. Intracranial tumor
    4. Concussion
    5. Encephalitis
    6. Epilepsy
    7. Lead encephalopathy
    8. Purulent meningitis
    9. Diencephalic syndrome
  - *B* Bulbar
    1. Bulbar poliomyelitis
    2. Bulbar palsy
  - *C.* Spinal
    1. Transverse myelitis
    2. Transection of cord
    3. Cervical or upper dorsal lesions
    4. Tabes dorsalis
  - *D.* Peripheral
    1. Polyneuritis
    2. [illegible]
- IV. [illegible]
    1. Coarctation of aorta
    2. Arteriovenous fistula
    3. Aortic regurgitation
    4. Senile atherosclerosis
    5. Congestive heart failure
- V. Psychogenic
- VI Dietetic
- VII Poisoning (endogenous or exogenous)
  - *A* [illegible]
- [illegible]
  - *A.* Gaisboeck's syndrome (polycythemia with hypertension)
  - *B.* Beriberi
  - *C.* Pink disease
  - *D* Postamputational
  - *E* Severe traumatic lesions
  - *F* Hemo- or myoglobinuria
  - *G* Emphysema

The above list of causes of secondary hyper*tension* is by no means final or complete. With the discovery of further causes of hyperten*sion*, more and more entities are likely to be added to the list in the near future

RENAL HYPERTENSION

The association between Bright's disease and hypertension has been known for many years. The frequent *relationship* of hypertension with pyelonephritis or hydronephrosis, on the other hand, has been established more recently. The fact that hypertension may be associated with bilateral or unilateral kidney disease has important diagnostic and therapeutic implications.

The high incidence and great variety of renal lesions demonstrable in cases of hypertension; the experimental production of hypertension by the clamping of renal arteries of dogs (Goldblatt et al., 1934); and the possible abolition of the hypertensive state through removal of a diseased kidney stressed the important relationship between the kidneys and high blood pressure. Following the experiments of Goldblatt and his associates, it was suggested that some cases of essential hypertension might be of renal origin, being caused by excessive elaboration of pressor substances by the ischemic kidneys. Such a viewpoint is no longer tenable in the light of more recent work. Present opinion, however, does ascribe a role of importance to the kidney in 10 to 15 per cent of cases (renal hypertension), in which disease of one kidney, or of both, bears a definite causal relationship to the hypertension

The actual role of *unilateral renal disease* in hypertension is difficult to establish for several reasons. (1) The association between the two conditions may be coincidental, the hypertension being of the essential, rather than the renal, type. (2) Proved renal hypertension, when of long duration, may fail to respond to removal of the diseased kidney. (3) A high level of pressure, recorded before nephrectomy, may be physiologic or psycho*genic rather than* caused by specific lesions. (4) The hypotensive response to nephrectomy does not necessarily prove a renal origin of the hypertension, since a transitory drop of blood pressure may accompany any form of major surgery. Only when a persistent drop of both diastolic and systolic blood pressure to normal level can be demonstrated after removal of an obviously damaged kidney, can the case be regarded as one of hypertension. Renal hypertension, although usually associated with advanced disease of the kidney, may occur early in the course of renal disease, if associated with vascular spasm or sclerosis.

Unilateral renal disease with renal hypertension may be of one of two types. (1) vascular, with obstruction of the renal artery from atherosclerosis, thrombosis, embolism, aneurysm, adhesion, or pressure by tumor or cyst, or because of a congenital anomaly (absence of renal artery or ectopic kidney); (2) parenchymal, in cases of unilateral pyelonephritis, hydronephrosis, renal tumor, tuberculous kidney, renal calculus, or perirenal hematoma.

CARDIAC FAILURE. The presence or absence of heart failure and its degree and type are of utmost importance. Pulmonary edema, paroxysmal nocturnal dyspnea, gallop rhythm, alternans, electrocardiographic evidence of myocardial damage, and refractoriness to treatment indicate a guarded prognosis. When several of these conditions are present, prognosis is definitely worse.

CORONARY INVOLVEMENT A history of episodes of precordial pain or myocardial infarction makes the outlook grave and uncertain, sudden death or further infections being possible during the subsequent course of the disease.

DIABETES. Diabetes predisposes to arteriosclerosis and nephrosclerosis; episodes of hyperglycemia, hypoglycemia, or coma may occur; early occurrence of coronary or cerebral infarcts is not unusual. Therefore, the prognosis for diabetic patients is usually worse.

SIZE OF HEART. Except in coronary disease (in which the outlook may be poor despite a normal heart size), the death rate in hypertension is roughly proportional to the degree of enlargement of the heart.

CEREBROVASCULAR ACCIDENTS Cerebral hemorrhage usually proves fatal within a few days; cerebral thrombosis tends to shorten the life span of hypertensive patients by several years.

TREATMENT. Early, appropriate, and intensive therapy, particularly for a cooperative patient, may affect the prognosis appreciably, especially when the essential hypertension is benign. Even in malignant hypertension, most of the ominous signs may disappear following therapy.

SECONDARY FORMS OF HYPERTENSION

Diastolic, or true, hypertension may be either *primary* (essential), with an obscure etiology (as in 80 to 90 per cent of cases), or *secondary* (symptomatic), with some demonstrable cause (as in 10 to 20 per cent).

Classification of Types of Secondary Hypertension

I. Renal or nephrogenic
- *A*. Affections of renal parenchyma
  1. Acute glomerulonephritis
  2. Chronic glomerulonephritis
  3. Chronic pyelonephritis
  4. Hydronephrosis
  5. Polycystic disease
  6. Diabetic glomerulosclerosis
  7. Renal calculi
  8. Infarction of kidney
  9. Renal tumor
  10. Hypernephroma
  11. Amyloidosis
  12. Scarring or trauma
  13. Radiation nephritis
  14. Ectopic kidney
  15. Hypogenesis
  16. Dystopia
  17. Nephrocalcinosis
  18. Necrotizing nephrosis
- *B* Affections of main renal arteries
  1. Atherosclerotic plaques
  2. Aneurysm
  3. Dissecting aneurysm
  4. Thrombosis
  5. Compression by tumor
- *C*. Affections of small renal vessels
  1. Polyarteritis nodosa
  2. Thromboangiitis obliterans
  3. Dermatomyositis
  4. Scleroderma
  5. Disseminated lupus erythematosus
  6. Embolic nephritis
  7. Lead poisoning
- *D* Affections of ureter and pelvis
  1. Calculus obstruction
  2. Kinking of ureter
  3. Pressure on ureter
  4. Pyelitis
- *E* Perirenal affections
  1. Perinephric abscess
  2. Tumor
  3. Hematoma
  4. Retroperitoneal affection
  5. Wilms's tumor

II Endocrine
- *A* Adrenal
  1. Hypercorticism (adrenocortical hyperfunction)
     - *a* Cushing's syndrome
     - *b* Adrenogenital syndrome
     - *c* Primary aldosteronism (Conn's syndrome)
     - *d* [illegible]
  2. [illegible] ...toma)
- *B* Pituitary
  1. Cushing's disease (basophil adenoma or hyperplasia)
  2. Eosinophil adenoma (rare)
  3. Chromophobe adenoma (rare)
- *C*. Thyroid
  1. Thyrotoxicosis (hyperthyroidism)
  2. Myxedema (hypothyroidism)
- *D* Ovarian
  1. Climacteric (menopausal)
  2. Arrhenoblastoma
  3. Toxemia of pregnancy
- *E* Parathyroid (rare): primary hyperparathyroidism (with nephrocalcinosis)

CHRONIC PYELONEPHRITIS. The importance of chronic *pyelonephritis* as a cause of renal hypertension, and its high incidence, have been recognized only recently. The condition may be unilateral or bilateral, is common in youthful subjects, particularly women, may follow acute pyelonephritic attacks or recurrent urinary infections, instrumental study of the bladder, urologic obstruction, impaction of renal calculus, enlarged prostate, septic fever, general debility, severe anemia, or neurogenic bladder. The *infection of the kidney* (usually bacterial) is of either the hematogenous (via the blood stream) or the ascending type (via the ureter). It is characterized by a gross pyuria with a massive quantity of pus in the urine, microscopic or frank hematuria, casts, and bacteria; low specific gravity of the urine, high blood urea, and other evidence of renal insufficiency Hypertension, which is a frequent complication, being twice as common in *patients with chronic pyelonephritis* as in normal controls, is usually severe, rapidly progressive, has a tendency to become malignant, and is often associated with encephalopathy, weakness, emaciation, backache, unexplained pyrexia, and facial puffiness Intravenous pyelography, by disclosing characteristic constriction, flattening, distortion, or dilatation of the pelvis or calyces, with shrinkage of one or both renal shadows, helps to establish the final diagnosis

DIABETIC NEPHROSCLEROSIS (KIMMELSTIEL-WILSON SYNDROME). First described by Kimmelstiel and Wilson (1936), diabetic nephrosclerosis is characterized clinically by the presence of diabetes (the causative factor), hypertension, massive proteinuria, nephrotic edema, diabetic retinopathy, arteriosclerosis, and renal insufficiency or uremia. Pathologically, the diagnostic lesion is a nodular or diffuse hyalinization of the glomerular tufts of the kidney. Irrespective of treatment, the course is invariably downhill, with death from uremia or congestive cardiac failure supervening in about 3 years.

ENDOCRINE HYPERTENSION

Abnormally high arterial blood pressure is a manifestation of several endocrine disorders, particularly those affecting the adrenal glands (adrenal hypertension). However, the exact role of endocrine factors *in the genesis* of hypertension has not as yet been elucidated.

Adrenal Hypercorticism. CUSHING'S SYNDROME. This syndrome is caused by overactivity of the adrenal cortex, or *is secondary to* adrenocortical tumor, bilateral cortical hyperplasia, basophil adenoma of the pituitary gland (Cushing's disease), hypothalamic disease, thymoma, or ovarian tumor. Cushing's syndrome is characterized by obesity (90 to 100 per cent of cases), hypertension (80 to 90 per cent), generalized edema, purple *striae atrophicae* over the abdomen, amenorrhea, virilism, plethoric appearance of the face, kyphosis, weakness, osteoporosis of bones, polycythemia, tendency to purpura, and mental symptoms.

Characteristic alterations of the serum electrolytes, including low blood potassium and chloride, normal sodium, and high carbon dioxide; abnormalities of protein, fat, and carbohydrate metabolism; disturbances of androgen-estrogen balance, and normal 17-ketosteroid with raised 11-oxysteroid and 17-hydroxycorticoid contents of blood and urine, confirm the clinical diagnosis The urine does not show a persistently alkaline reaction or a low and fixed specific gravity, as it does in primary aldosteronism.

In pituitary basophilism (Cushing's disease), excess liberation of corticotropin from the anterior lobe of the pituitary brings about adrenocortical hyperfunction with excessive production of adrenocorticotropic hormone (ACTH).

When diabetes and (more rarely) gynecomastia are associated with Cushing's syndrome, the condition is referred to as the "Achard-Thiers syndrome."

PRIMARY ALDOSTERONISM (CONN'S SYNDROME). Aldosterone, a steroid or mineralocorticoid, with potent sodium-retaining activity and a formula of 18-oxycorticosterone, has been isolated from the adrenal cortex. Conn (1955) described a clinical syndrome caused by excessive secretion of aldosterone by the adrenal cortex, and characterized by hypertension, recurrent episodes of muscle weakness, tetany, polyuria, polydipsia, paresthesias, and absence of edema. Numerous cases of Conn's syndrome, secondary to adrenocortical adenoma, carcinoma, or hyperplasia, have been reported. Other characteristics of Conn's syndrome are a high blood pH or alkalosis, high carbon dioxide content of blood, *low serum* potassium (hypokalemia), low serum chloride (hypochloremia), normal or increased serum

Diagnosis. In most cases of renal hypertension, there is a history of episodes of urinary infection, hematuria, puffiness of the face, or generalized edema. Renal involvement in hypertension may also be suggested by the age of the patient (more common in young subjects), fairly acute onset, febrile and rapidly progressive course, negative family history of hypertension, pallor, urinary abnormalities, altered blood chemistry, and abnormal pyelograms

SPECIAL TESTS FOR RENAL HYPERTENSION

1. Blood chemistry
   - *a* Serum proteins (total protein, albumin, globulin)
   - *b* Blood creatinine
   - *c* Calcium and phosphorus content of plasma
   - *d* Alkaline phosphatase
   - *e.* Blood uric acid
   - *f.* Lupus erythematosus cell preparation
2. Excretory tests
   - *a.* Creatinine clearance test
   - *b* Congo red excretion test
   - *c.* Excretion of sodium and water
3. Urinary tests
   - *a.* Urine culture
   - *b* Counts of casts and cells
   - *c.* Bence-Jones protein
4. Radiologic tests
   - *a.* Intravenous pyelogram
   - *b.* Retrograde pyelogram
   - *c.* Radioactive Diodrast
   - *d.* Renal angiogram
5. Biopsies
   - *a.* Renal biopsy
   - *b.* Skin and muscle biopsies
6. Tests for hypertension of unilateral kidney origin

Ingenious tests have been devised for facilitating the diagnosis of hypertension of unilateral renal origin, a type of hypertension frequently amenable to nephrectomy.

HOWARD'S TEST. Based on the assumption that in unilateral kidney disease there is usually some degree of obstruction of the renal artery or a major branch, causing renal ischemia, this test depends on a differential excretion of sodium and water from the kidney. It may be positive even with a normal pyelogram.

The patient, who is on a normal diet for 3 to 4 days, is given 200 ml water to drink every 15 min for 1 hr Urine is obtained simultaneously from each kidney through separate catheters. The test ends when 50 ml urine is obtained from any one kidney. If the volume of urine is reduced by 60 per cent or more in one kidney as compared with the other, and sodium excretion by 16 per cent or more, the test is positive, and nephrectomy is a suitable means of therapy.

This test is helpful for hypertensive patients with one-sided kidney disease, as well as for rapidly progressive or refractory forms of hypertension. A high blood urea nitrogen without dehydration, being evidence of advanced bilateral disease, rules out the test.

WINTER'S RADIOISOTOPE TRACER TEST. Following an intravenous injection of iodine^{131}-labeled Diodrast, the rates of accumulation and disappearance in the kidney areas of the radioisotope are estimated by means of external monitors This so-called *radioactive renogram test* represents a rapid form of screening, useful for selection of patients for nephrectomy.

Special Forms of Nephrogenic Hypertension. GLOMERULONEPHRITIS. In acute *diffuse glomerulonephritis*, hypertension is usually of acute onset, moderate degree, and short duration, it is invariably accompanied by anasarca or edema, a puffy face, hematuria, proteinuria, oliguria, backache, malaise, and low fever, it is preceded by a history of septic sore throat, scarlet fever, or other infection. Blood pressure usually returns to normal within 2 to 7 weeks. The urine is red, dirty-brown, or smoky, and contains albumin, red cells, and blood casts, the blood shows urea retention and multiple evidence of impaired renal function The acute onset of hypertension may cause left ventricular failure, or left and right failure, retinopathy, or encephalopathy.

Chronic diffuse glomerulonephritis, which may follow an acute or subacute phase of nephritis, a nephrotic syndrome, or a "leaky" kidney with albuminuria, is invariably accompanied by hypertension and is associated with renal insufficiency The hypertension of chronic nephritis may be moderate or severe; it is usually fixed and may attain levels of over 250 systolic and 150 diastolic, it is associated with high blood urea, nonprotein nitrogen, and creatinine, anemia, and proteinuria; hyaline, granular, and epithelial casts, and red blood cells are found in the urine. With a tendency to increasing renal and cardiac insufficiency, the disease usually terminates, after a variable course, in fatal uremia.

Sustained or persistent hypertension, otherwise indistinguishable from essential hypertension, occurs more frequently in pheochromocytoma than does the classical, paroxysmal form of hypertension. Adrenal tumors associated with persistent hypertension are usually small and have a total catecholamine content of less than 80 mg, 90 to 97 per cent of which is norepinephrine (Goldenberg, 1950). They are either completely asymptomatic or associated with bizarre symptoms or symptoms suggestive of malignancy or Addison's disease. The hypertension may or may not be associated with symptoms and signs of hypermetabolism and hyperglycemia. One may suspect the adrenomedullary origin of the hypertension if there is history of paroxysmal attacks of hypertension, hyperglycemia with glycosuria, abnormal glucose tolerance curves, tachycardia, postural hypotension, low-grade pyrexia, normal reaction to cold-pressor stimuli, leucocytosis, raised basal metabolic rate, and positive (radiologic, chemical, or pharmacologic) screening tests. In the absence of these features, the condition is likely to be mistaken for essential hypertension.

DIAGNOSIS. Diagnosis of medullary hyperfunction is of the utmost importance, because of its possible surgical correction. It is based on certain typical clinical features and special diagnostic tests:

Radiologic Tests. Roentgenograms of the abdomen may reveal or outline a mass, provided it is not too small or anomalously situated, and especially when it is calcified. At times, secondary spreads of the tumor, if malignant, may be detected by radiography. Tomography or planigraphy, after perirenal insufflation with air or oxygen, may disclose the outlines of the tumor. On rare occasions, an x-ray of the chest may reveal ... [illegible]

t

t ... [illegible] ... cent of pheochromocytomas. They depend on the use of (1) adrenergic blocking agents (adrenolytic drugs or antagonists to catecholamines), such as Regitine (pentolamine) and Benzodioxane (Piperoxan), (2) adrenal stimulants or pressor agents, such as histamine acid phosphate base, Mecholyl, hexamethonium bromide, and tetraethylammonium chloride.

Regitine Test. Although less specific, Regitine is usually prefer... [illegible]

less likely [illegible]

rise of bl... [illegible] ... A drop of pressure of over 35/25, after an intravenous injection of 5 mg of the drug, is considered diagnostic. *False-positive reactions* may be noted after sedatives or narcotics, and in patients with malignant, renal, or essential hypertension. *False-negative reactions* may be due to administration of Apresoline or other hypotensive drugs; therefore, such drugs must be discontinued for a week before the test.

Histamine Test. In normotensive and mildly hypertensive subjects with suspected medullary hyperfunction, an intravenous injection of 0.025 to 0.05 mg histamine acid phosphate (or of 300 mg tetraethylammonium chloride or 15 mg hexamethonium bromide) may help to confirm the diagnosis by provoking a hypertensive crisis.

Chemical Tests. A direct, chemical determination of the catecholamine (norepinephrine and epinephrine) content of blood or urine (24-hr excretion) is the most dependable of all tests for pheochromocytoma. The urinary excretion of sympathomimetic amines may rise in such cases from the normal of 14 to 40 mg norepinephrine to between 600 and 2,700 mg/day. A *false-positive reaction* may arise at times from raised intracranial tension, renal insufficiency, or anxiety neurosis.

Exploratory Laparotomy. A laparotomy may prove necessary in suspected cases of pheochromocytoma, not only to establish the diagnosis or locate the tumor, but as a preliminary measure prior to surgical removal.

TREATMENT. The hypertension of pheochromocytoma responds promptly or dramatically to surgical removal of the tumor. It should be kept in mind that the operation, even if carried out with every possible precaution (such as slow intravenous drip of norepinephrine), carries a high mortality rate.

Menopausal Hypertension. The incidence of menopausal hypertension has been variously reported as between 1 and 50 per cent. It is a mild and benign form of hypertension, which may be either transitory or persistent, and is associated with a host of symptoms, such as irregular or scanty periods, hot flushes, feeling of cold, palpitation, emotional instability, and fine tremors, and is common in women during the menopause. When menopausal hypertension occurs in conjunction with obesity, osteoarthritis of the knee joints, and tender subcutaneous nodules, the syndrome is called Gram's syndrome.

P... [illegible]

ing [illegible]

It ... [illegible] ... one of several causes: (1) pregnancy toxemia, either preeclamptic or eclamptic; (2) essential hypertension, associ-

sodium, a persistently alkaline urine with low and fixed specific gravity, normal 17-hydroxycorticoid, 11-oxysteroid, and 17-ketosteroid excretions, and an increased content of aldosterone. The hypertension, even when severe or malignant, usually responds to surgical removal of the tumor.

SECONDARY ALDOSTERONISM. Hypersecretion of aldosterone, of noncortical origin, may arise in states of generalized edema, such as congestive failure, nephrosis, or liver cirrhosis It may occur after excessive loss of fluid, as in neglected diabetes mellitus, diabetes insipidus, or salt-losing nephritis; after excessive administration of diuretics (such as mercurials or Diamox); or after violent exercise, salt-free diet, or venesection

ADRENOGENITAL SYNDROME A rare syndrome of cortical hypersecretion, associated with androgen-estrogen imbalance, may be caused by tumor or hyperplasia of the adrenal cortex, hypothalamic disease, pineal tumor, ovarian disease, or Leydig cell testicular tumor It is characterized by hypertension, *virilism*, *hirsutism*, small breasts, amenorrhea, and enlarged clitoris in women; by feminization, small genitals, and loss of libido in men While urinary excretions of 17-ketosteroid and estrogen are increased, that of 11-17-oxysteroid remains unaltered. Unlike all other forms of hypertension, adrenogenital hypertension may be relieved by the oral administration of cortisone or *prednisone*.

DIAGNOSIS The recognition of adrenal hypercorticism depends on the general appearance of the patient, sexual characteristics, hypertension, weakness, fatigability; steroid (17-ketosteroid, 11-oxysteroid, 17-hydroxycorticoid, and aldosterone) content of blood and urine, biochemical alterations of blood and urine (including carbon dioxide, chloride, sodium, potassium, pH, protein-bound iodine, sugar, and catecholamines); excretory pyelograms, x-rays of adrenal glands, perirenal insufflation with oxygen; and exploratory laparotomy.

Pheochromocytoma (*Adrenomedullary Hypertension*). Numerous cases of pheochromocytoma, associated with paroxysmal or sustained hypertension, have been reported in medical literature since Frankel's description (1886). It is an interesting, but infrequent, usually benign tumor, arising from the chromaffin cells or pheochromocytes of one or both adrenal medullas (in 90 per cent of cases) or from extramedullary sites, such as the pa ganglia (embedded within the sympathe ganglia), and the aortic chromaffin bodies organ of Zuckerkändl, at the root of the in rior mesenteric artery). The pheochromo toma (or *chromaffinoma*), by discharging cessive amounts of normal catecholamines (inephrine and norepinephrine), is the cause an interesting form of hypertension. The tun is usually a circumscribed, spherical or ov solid, tan-colored or grayish-white mass, u ally single (in 90 per cent of cases) a benign (in 90 per cent), arising at any a from 20 to 50 years (with a peak incidence the age of 44 years). It may arise in conju tion with neurofibromatosis or the Stur Weber syndrome.

The *hypertension occurs* in about 0.5 cent of all cases of hypertension, and may either paroxysmal or persistent. Paroxysm attacks of hypertension, when arising in p ochromocytoma, are almost pathognomon Arising either spontaneously (usually in morning hours) or after exercise, emotion, eration, or abdominal palpation, the *paroxys of hypertension*, which usually last for 5 30 min (for days at times), occur cyclically irregularly, from several times a day to on or twice a year. They are characterized by sudden and steep rise of both the systolic a the diastolic blood pressure. They are, as rule, associated with severe and generaliz headache, drenching sweat, tremors, palpi tion, pallor or cyanosis, vasomotor phenome of the skin, paresthesias, dilated pupils, naus vomiting, abdominal cramps, rapid beating the heart, extrasystoles, postural hypotensi restlessness, nervousness, low-grade pyrex albuminuria, increase of basal metabolic r (about +20 or more), glycosuria, and h perglycemia The clinical manifestations a caused by the excessive liberation in the blo of norepinephrine [which tends to cause d fuse vasoconstriction, bradycardia, and systo and diastolic hypertension (without changes cardiac output)] and epinephrine [which ten to cause diffuse vasodilatation (except in t vessels of skin, kidneys, and lungs), systo hypertension, diastolic hypotension, tachyca dia, and increased cardiac output]. The hype tensive paroxysms of pheochromocytoma us ally subside spontaneously, being followed times by facial flushing and generalized wea ness.

ated with or aggravated by the state of pregnancy; (3) urologic complication of pregnancy, such as pyelonephritis or glomerulonephritis; (4) sodium and water retention.

HYPERTENSION OF PREGNANCY TOXEMIA. It frequently occurs during the third trimester of pregnancy (earlier, at times, in association with vesicular mole) or just after delivery and is particularly common in women with renal disease The increase of pressure is usually moderate and is associated with sudden gain in body weight and severe edema (particularly of the face and hands). There are massive albuminuria, abundant red cells and casts in the urine, early retinopathy with vascular spasm, convulsions or (when associated with eclampsia) positive Ascheim-Zondek test, increase of blood uric acid, low serum albumin, and normal blood urea (unless the form is complicated by kidney disease, malignant hypertension, or adrenal necrosis). Although associated with a mortality rate of over 25 per cent for the fetus and of 1 to 2 per cent for the mother, pregnancy toxemia promptly responds to artificial termination of the pregnancy.

The etiology of hypertension in pregnancy toxemia remains obscure in spite of numerous investigations The two most favored viewpoints attribute the hypertension to (1) placental ischemia or premature vascular aging of the placenta, causing absorption of autolytic pressor substances, or (2) hormonal imbalance, caused by a primary metabolic or vascular anomaly of the placenta, and leading to early senility, with premature withdrawal of steroid hormones

NEUROGENIC HYPERTENSION

Lesions of the central or autonomic nervous system, when involving the vasomotor centers of the diencephalon, pons, or medulla, or when associated with raised intracranial tension, may bring about arterial hypertension, somewhat similar to that of pheochromocytoma

Neurogenic or cerebral hypertension, as in adrenomedullary hyperfunction, is either paroxysmal or sustained and is likely to develop into hypertensive encephalopathy or the malignant syndrome. It is frequently associated with symptoms and signs of sympathetic hyperactivity, such as flushing, sweating, tachycardia, abdominal pain, and vasomotor phenomena Because of the frequently increased catecholamine content of the blood and the prompt response to sympatholytic drugs, hypertension of neurogenic origin is said to be mediated through the sympathetic system.

Hypertensive Diencephalic Syndrome (Page). This is a syndrome of young or middle-aged women with labile hypertension and symptoms similar to those induced by stimulation of the diencephalon in man. The syndrome is associated with hypertensive episodes, patchy blushing of the face and upper part of the chest, cold and dusky, blue or pale extremities, localized sweating, lacrimation, tachycardia, increased basal metabolic rate, and hyperperistalsis The attacks may arise spontaneously or after emotional excitement, and may lead to an erroneous diagnosis of thyrotoxicosis. Subtotal thyroidectomy fails to improve the condition.

The differential diagnosis between neurogenic and adrenomedullary hypertension may prove extremely difficult because of the common feature of paroxysmal hypertension The diagnosis of neurogenic hypertension may have to depend on the demonstration of the primary neurologic disease, exclusion of adrenomedullary overaction, x-ray of skull and abdomen, electroencephalographic and cerebrospinal fluid examinations, arteriograms, ventriculograms, and demonstration of lead or porphyria in the urine

Treatment Neurogenic hypertension may be treated by removal of the causative lesion (when possible), administration of sympatholytic drugs, or tapping of cerebrospinal fluid, in order to reduce the intracranial tension.

COARCTATION OF AORTA

This condition is discussed in Part 6, Chaps 2 and 3

tricular strain A *heaving apex beat* and an *increased long diameter of the heart* reveal hypertrophy of the left ventricle A *triple rhythm* (*gallop rhythm*) is evidence of left ventricular strain and of increased left atrial pressure It may be of either the ventricular or the atrial type owing to respective intensification of either the 3d or the 4th heart sound. The meaning of both types is similar, because in the first case, the triple rhythm indicates stronger atrial contraction, in the second, more tumultuous passive ventricular filling In both cases, there is a higher left atrial pressure.

Systolic apical and aortic murmurs are common. The first reveals some dilatation of the mitral ring; the second, some dilatation of the aorta. If mitral valvular sclerosis is excluded (recent appearance of the murmur), the apical murmur is evidence of left ventricular strain and, possibly, of failure. As far as the aortic murmur is concerned, it simply indicates a high level of arterial pressure and a "relative" aortic stenosis (flow murmur).

A ringing 2d aortic sound is the direct result of hypertension It may be followed by a *short, blowing, diastolic murmur*, probably due to some degree of sclerosis of the aortic leaflets

Even though the borderline between left ventricular hypertrophy, left ventricular strain, and left ventricular failure is not always easy to draw, especially on purely clinical grounds, certain symptoms and signs indicate more severe repercussions on the heart, and definite failure (Table 12-3).

Orthopnea and *paroxysmal dyspnea* involve a complex cardiovascular and reflex mechanism which is partly based on the results of increased residual blood within the left ventricle, increased left atrial and pulmonary venous pressures, and higher right ventricular and pulmonary arterial pressures In other words, the various elements of the paroxysm lead to a readjustment of work whereby the right ventricle increases its work and maintains a high pressure, the pulmonary circulation is distended, and the left atrial filling pressure is greater. The left ventricle dilates, and the greater length of its fibers allows an increase of work A *loud* P_2 is usually heard if this readjustment of pressures becomes permanent.

Paroxysmal pulmonary edema of the hypertensive patient has a complex mechanism. Its underlying phenomena are left ventricular strain and consistently high pulmonary arterial and venous pressures (see Part 18, Chap. 13). Usually, one of several mechanisms leads to peripheral vasoconstriction, redistribution of the blood, and sudden congestion of the lungs. However, several other complex phenomena, including reflex and humoral elements, are involved in the production of the attack.

Among the signs of left ventricular failure, *tachycardia* is common. *Pulsus alternans* has a severe meaning, *revealing a profound* biochemical deterioration of the myocardium. *Pulmonary rales* indicate subacute *pulmonary* edema. A *diastolic rumble at the apex and* midprecordium is probably due to severe dilatation of the left *ventricle with "relative"* mitral stenosis It may be a transitory murmur and disappear after a few weeks with improvement of the cardiac condition It is more common in cases with coronary heart disease and diffuse fibrosis of the left ventricle.

THE ELECTROCARDIOGRAM

The electrocardiogram is useful in ascertaining whether or not there are cardiac repercussions of hypertension. It may reveal *evidence of left ventricular hypertrophy* consisting of *increased voltage of the QRS complex in the limb leads* (with deeper S wave in V_1 to V_2 and taller R wave in V_5 to V_6); *increased duration of the QRS* complex, which reaches 0 10 to 0 11 sec in the limb leads; *and a delay of the R* wave over the Q wave in V_5 to V_6 greater than 0.05 sec.

Other laboratory data may be of importance (see the classification on page 12–46).

THE PHONOCARDIOGRAM

The phonocardiogram may reveal the existence of an *apical systolic murmur* (relative mitral insufficiency), an *apical diastolic murmur* (*relative* mitral stenosis), or both (Fig. 12-3). The latter can be differentiated from the murmur of organic mitral stenosis through positive data (high voltage, late appearance, wide diffusion, initiation by the vibration of a large 3d sound) and negative data (lack of an opening snap of the mitral valve, normal interval between the Q wave and 1st sound). It may also reveal *an aortic systolic murmur* and an aortic *diastolic murmur.* The former is seldom diamond-shaped, it is usually short and

7

Graphic data in hypertension

ALDO A. LUISADA

Arterial hypertension may or may not be accompanied by obvious changes of cardiac function. While it is logical to admit that sustained hypertension always leads to some degree of left ventricular hypertrophy, the latter may be so mild that no evidence can be found during life and only autopsy may reveal a slight increase in the weight of the heart, in the thickness of the left ventricular wall, and in the length of the outflow chamber of the left ventricle.

Although symptoms and signs have already been described, a brief listing of them will be useful here (Table 12-3) because graphic data necessarily reflect changes also revealed by clinical data.

The repercussions of hypertension may include exertional dyspnea, palpitation or precordial pain, dry cough, and sleeplessness

Dry cough may be caused by a reflex from the aortic arch or carotid sinus receptors *Sleeplessness* may be a purely cerebral disturbance. Therefore, neither of these symptoms, per se, indicates cardiac involvement *Exertional dyspnea* and *palpitation* are usually evidence of some decrease of cardiac reserve and, therefore, are the result of the constant high load placed upon the left ventricle. *Precordial pain* reveals the increased blood demand of the left ventricle, which is further increased by exertion. As it indicates coronary insufficiency, e.g , a disproportion between blood supply and blood demand, it is more likely to occur when there is some degree of coronary rigidity due to atherosclerosis.

The physical signs of *cardiac repercussions* include the following.

Premature ventricular contractions, a second cause of palpitation, are revealed by irregularities of the pulse and of the heart sounds. They indicate increased excitability of the myocardium, usually occurring in the stage of ven-

TABLE 12-3 CARDIAC SYMPTOMS AND SIGNS OF HYPERTENSIVE HEART DISEASE AND LEFT VENTRICULAR FAILURE

Hypertensive Heart Disease		*Left Ventricular Failure*	
Symptoms	*Signs*	*Symptoms*	*Signs*
Exertional dyspnea Palpitation Dry cough Sleeplessness Precordial pain	Premature contractions Heaving apex beat Triple rhythm (gallop) Systolic apical and aortic murmurs Ringing A_2 followed by a short blowing murmur	Orthopnea Paroxysmal dyspnea (Paroxysmal pulmonary edema)	Tachycardia Loud P_2 Pulsus alternans Diastolic apical rumble Basal pulmonary rales

tricular strain A *heaving apex beat* and an *increased long diameter of the heart* reveal hypertrophy of the left ventricle A *triple rhythm (gallop rhythm)* is evidence of left ventricular strain and of increased left atrial pressure. It may be of either the ventricular or the atrial type owing to respective intensification of either the 3d or the 4th heart sound. The meaning of both types is similar, because in the first case, the triple rhythm indicates stronger atrial contraction, in the second, more tumultuous passive ventricular filling. In both cases, there is a higher left atrial pressure

Systolic apical and aortic murmurs are common The first reveals some dilatation of the mitral ring, the second, some dilatation of the aorta If mitral valvular sclerosis is excluded (recent appearance of the murmur), the apical murmur is evidence of left ventricular strain and, possibly, of failure. As far as the aortic murmur is concerned, it simply indicates a high level of arterial pressure and a "relative" aortic stenosis (flow murmur).

A ringing *2d aortic sound* is the direct result of hypertension It may be followed by a *short, blowing, diastolic murmur*, probably due to some degree of sclerosis of the aortic leaflets

Even though the borderline between left ventricular hypertrophy, left ventricular strain, and left ventricular failure is not always easy to draw, especially on purely clinical grounds, certain symptoms and signs indicate more severe repercussions on the heart, and definite failure (Table 12-3)

Orthopnea and *paroxysmal dyspnea* involve a complex cardiovascular and reflex mechanism which is partly based on the results of increased residual blood within the left ventricle, *increased* left atrial and pulmonary venous pressures, and higher right ventricular and pulmonary arterial pressures In other words, the various elements of the paroxysm lead to a readjustment of work whereby the right ventricle increases its work and maintains a high *pressure*, the pulmonary circulation is distended, and the left atrial filling pressure is greater The left ventricle dilates, and the greater length of its fibers allows an increase of work A *loud* P_2 *is* usually heard if this readjustment of pressures becomes permanent.

Paroxysmal pulmonary edema of the hypertensive patient has a complex mechanism Its underlying phenomena are left ventricular strain and consistently high pulmonary arterial and venous pressures (see Part 18, Chap. 13). Usually, one of several mechanisms leads to peripheral vasoconstriction, redistribution of the blood, and sudden congestion of the lungs However, several other complex phenomena, including reflex and humoral elements, are involved in the production of the attack.

Among the signs of left ventricular failure, *tachycardia* is common. *Pulsus alternans* has a severe meaning, revealing a profound biochemical deterioration of the myocardium. *Pulmonary rales* indicate subacute pulmonary edema. A *diastolic rumble* at the apex and midprecordium is probably due to severe dilatation of the left ventricle with "relative" mitral stenosis It may be a *transitory murmur* and disappear after a few weeks with improvement of the cardiac condition It is more common in cases with *coronary* heart disease and diffuse fibrosis of the left ventricle.

THE ELECTROCARDIOGRAM

The electrocardiogram *is useful in* ascertaining whether or not there are cardiac *repercussions* of hypertension. It *may reveal evidence of left ventricular hypertrophy* consisting of *increased voltage of the QRS* complex in the limb leads (with deeper S wave in V_1 to V_2 and taller R wave in V_5 to V_6), *increased duration of the QRS* complex, which reaches 0 10 to 0 11 sec in the limb leads; and *a delay of the* R wave over the Q wave in V_5 to V_6 greater than 0 05 sec

Other laboratory data may be of importance (see the classification on page 12–46).

THE PHONOCARDIOGRAM

The phonocardiogram may reveal the existence of an *apical systolic murmur* (relative mitral insufficiency), an *apical diastolic murmur* (relative mitral stenosis), or both (Fig 12-3) *The* latter can be differentiated from the murmur of organic mitral stenosis through positive data (high voltage, late appearance, wide diffusion, initiation by the vibration of a large *3d sound*) and negative data (lack of an opening snap of the mitral valve, normal interval between the Q wave and 1st sound). It may also reveal an *aortic systolic murmur* and an *aortic diastolic murmur.* The former is seldom diamond-shaped, it is usually short and

7

Graphic data in hypertension

ALDO A. LUISADA

Arterial hypertension may or may not be accompanied by obvious changes of cardiac function. While it is logical to admit that sustained hypertension always leads to some degree of left ventricular hypertrophy, the latter may be so mild that no evidence can be found during life and only autopsy may reveal a slight increase in the weight of the heart, in the thickness of the left ventricular wall, and in the length of the outflow chamber of the left ventricle.

Although symptoms and signs have already been described, a brief listing of them will be useful here (Table 12-3) because graphic data necessarily reflect changes also revealed by clinical data.

The repercussions of hypertension may include exertional dyspnea, palpitation or precordial pain, dry cough, and sleeplessness

Dry cough may be caused by a reflex from the aortic arch or carotid sinus receptors *Sleeplessness* may be a purely cerebral disturbance. Therefore, neither of these symptoms, per se, indicates cardiac involvement *Exertional dyspnea* and *palpitation* are usually evidence of some decrease of cardiac reserve and, therefore, are the result of the constant high load placed upon the left ventricle. *Precordial pain* reveals the increased blood demand of the left ventricle, which is further increased by exertion. As it indicates coronary insufficiency, e.g., a disproportion between blood supply and blood demand, it is more likely to occur when there is some degree of coronary rigidity due to atherosclerosis.

The physical signs of *cardiac repercussions* include the following.

Premature ventricular contractions, a second cause of palpitation, are revealed by irregularities of the pulse and of the heart sounds. They indicate increased excitability of the myocardium, usually occurring in the stage of ven-

TABLE 12-3 CARDIAC SYMPTOMS AND SIGNS OF HYPERTENSIVE HEART DISEASE AND LEFT VENTRICULAR FAILURE

Hypertensive Heart Disease		*Left Ventricular Failure*	
Symptoms	*Signs*	*Symptoms*	*Signs*
Exertional dyspnea Palpitation Dry cough Sleeplessness Precordial pain	Premature contractions Heaving apex beat Triple rhythm (gallop) Systolic apical and aortic murmurs Ringing A_2 followed by a short blowing murmur	Orthopnea Paroxysmal dyspnea (Paroxysmal pulmonary edema)	Tachycardia Loud P_2 Pulsus alternans Diastolic apical rumble Basal pulmonary rales

PULSE TRACINGS

Pulse tracings may reveal the existence of *pulsus alternans*, a phenomenon having a serious meaning, even though patients with this typical abnormality may improve and even recover. They may show the results of irregularities of the cardiac rhythm, usually caused by ventricular premature contractions.

BALLISTOCARDIOGRAM

The *ballistocardiogram* (BCG) usually has large complexes in hypertension without severe strain Whenever the heart is undergoing strain or failure, several abnormalities can be noticed It is difficult to separate the parts played by atherosclerosis of the aorta, abnormal left ventricular contraction, and peripheral vasoconstriction in causing the abnormal patterns which can be observed Undoubtedly, the more atypical the pattern, the less favorable the prognosis

CIRCULATION TIMES—RADIOCARDIOGRAPHY

Circulation times are normal as long as the left ventricle is not failing When the left ventricle fails, *arm-to-tongue time* (Decholin) becomes longer while *arm-to-lung time* (ether) is still normal The prolongation of the former is largely due to increase of the residual blood left in the left ventricle at the end of systole and to slower circulation from the pulmonary capillaries, through the left heart, to the arteries of the systemic circulation. A similar mechanism causes a prolongation of the L wave of the *radiocardiogram* (Fig. 12-5), which is a witness to the longer persistence of injected radioactive materials within the left ventricle. The valley between the R and L waves becomes less marked.

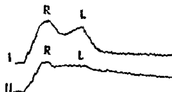

Fig. 12-5. Scheme of the radiocardiogram in hypertensive heart disease. I, normal; II, left ventricular failure; prolongation of L wave; less evident drop of curve between R and L waves.

The following schema presents all the above data in their progressive sequence and in order of increased severity.

PROGRESSIVE EVIDENCE OF CARDIAC EFFECTS OF HYPERTENSION

1. Exertional dyspnea, palpitation, cough, premature beats, heaving apex beat, ECG evidence of hypertrophy, systolic basal murmur, ringing A_2, large BCG waves
2. Tachycardia, systolic apical murmur, triple rhythm, ECG evidence of anterolateral ischemia, x-ray signs of enlarged left ventricle
3. Paroxysmal dyspnea, prolonged 1st apical sound, diastolic apical rumble, short aortic diastolic murmur, atypical BCG pattern, ECG evidence of bundle branch block or intraventricular block, increased arm-to-tongue time, pulsus alternans
4. Orthopnea, paroxysms of pulmonary edema, x-ray evidence of total cardiac enlargement, increased circulation times, small BCG waves, evidence of venous and hepatic engorgement

LABORATORY DATA REVEALING HYPERTENSIVE HEART DISEASE

1. ECG
   a. Evidence of left ventricular hypertrophy
   b. Evidence of anterolateral ischemia
   c. Evidence of diffuse coronary insufficiency
   d. Evidence of myocardial fibrosis

2. Phonocardiogram
   a. Apical murmurs: Systolic Diastolic
   b. Aortic murmurs: Systolic Diastolic
   c. Triple rhythm
   d. Prolonged 1st sound
   e. Loud (split) 2d aortic sound

3. X-ray
   a. Convexity of left ventricular border
   b. Elongation of cardiac shadow (posterior enlargement)
   c. Increased pulsations of aorta (small pulsations of left ventricle)

4. Low-frequency tracing
   a. Positive, tall apical pulsation
   b. Negative epigastric pulsation

5. BCG
   a. Large waves, small waves
   b. Abnormal pattern

6. Circulation time or radiocardiography
   a. Prolonged arm-to-tongue
   b. Delayed end of L wave

consists of two to three extremely low-pitched vibrations (aortic vibrations) with superimposition of other, higher-pitched vibrations in early systole. The latter is also usually short (three to six vibrations in decrescendo) and starts with a 2d sound of increased magnitude (Fig. 12-3).

While the basal murmurs are the direct result of hypertension and have no special meaning, the apical murmurs result from dilatation of the left ventricle and indicate progressive deterioration from strain to failure. The diastolic murmur carries with it a more serious meaning than the systolic. In its interpretation, it should be kept in mind that severe coronary heart disease or syphilitic aortic insufficiency may favor it.

A *triple rhythm (gallop rhythm)* is a common finding. It may be caused by intensification or higher pitch of either the 3d or the 4th sound. Larger magnitude, higher pitch, and more numerous vibrations indicate more serious functional strain and a higher left atrial pressure—therefore, a proportionally more serious prognosis.

THE LOW-FREQUENCY TRACINGS OF THE PRECORDIUM AND EPIGASTRIUM

These tracings may supply data indicating enlargement of the left ventricle. When this chamber is enlarged through hypertrophy and dilatation, the tracing recorded at the apex (old term, *apex cardiogram*) reveals a tall, squarish or conical plateau in systole, frequently preceded by a high presystolic wave (atrial contraction). On the other hand, the *epigastric tracing* presents a deep, inverted wave in systole, which at times is like a mirror image of that of the apex (Fig. 12-4). These findings are due to the powerful contraction of the heart (the apex moves forwards and upwards during systole) and also to the stronger atrial contractions.

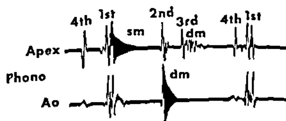

Fig. 12-3. Scheme of possible changes of phonocardiogram in hypertension. Apex, large 4th (atrial) sound causing a triple rhythm; faint systolic murmur, large 3d sound with "functional" diastolic rumble. Aorta, large 2d sound, short, early diastolic murmur.

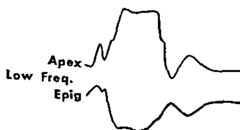

Fig. 12-4. Scheme of the low-frequency tracings in hypertension. Positive plateau at apex, negative pulsation at epigastrium, indicating left ventricular enlargement.

jor culprit and that lowering of blood pressure can delay or reverse many of the pathologic sequelae of hypertension.

SELECTION OF PATIENTS REQUIRING HYPOTENSIVE THERAPY

In general, if the disorder has been present for 8 years or more, and in that time no evidence of cerebral disease has become apparent, the arterioles of the optic fundi show only mild arteriolar changes without hemorrhage, exudate, or papilledema, the heart is within normal size, the electrocardiogram is normal or shows only left axis deviation, and the urine is free of albumin, it is clear that the disease is following a benign course and there is no indication for drastic therapy. Reassurance, simple sedation (e g , barbiturates), and reasonable rules of healthy, temperate living are adequate treatment Patients of this type will, on the average, live to within 3 to 4 years of their normal life expectancy without any treatment

On the other hand, individuals with hypertension of less than 8 years' duration who already show cardiac involvement (such as marked cardiac hypertrophy, left ventricular hypertrophy on the electrocardiogram, precordial pain, congestive failure), or severe changes in the optic fundi (hemorrhage, exudate, or papilledema), or evidence of cerebrovascular disease, or albuminuria have shown that they cannot tolerate their current levels of blood pressure. They probably have some degree of associated atherosclerosis as well. These patients with clear evidence of hypertensive cardiovascular disease should receive treatment.

There is no disagreement that patients in the accelerated or malignant phase of hypertension should be treated, there is little disagreement that patients with overt evidence of cerebral, cardiac, or renal involvement from hypertension should be treated Patients in this latter group who have required from 15 to 25 years to develop these complications can be assumed to have a considerable degree of atherosclerosis. Decision concerning therapy is most debated in the young or middle-aged person with labile blood pressure or with fixed high diastolic levels At present, patients with labile blood pressure should be treated with the safest of the sedative or "tranquilizing" drugs, fixed high diastolic pressure, especially in the young or middle-aged male, requires therapy. Too often these patients, "benign" by the usual criteria of lack of objective evidence of hypertensive cardiovascular disease, develop cerebral attacks, myocardial infarction, or renal insufficiency. There is not as yet any proof that hypotensive therapy will avert these untoward events but, in the absence of specific therapy, it seems worthwhile to attempt to lower the blood pressure.

AIM OF THERAPY

Some patients with hypertension have demonstrated their tolerance of the disease and should not be treated with potent hypotensive agents. Elderly persons, especially those with a history of long-standing hypertension (15 years or more) and *no evidence of hypertensive disease* other than moderate enlargement of the left ventricle, or mild arteriolar *changes in the* optic fundi, should be left free of dietary or drug restrictions. Patients with systolic elevations but diastolic levels of *100 or less*, especially if they are 60 years of age or older, require no hypotensive medication. Persons in their twenties without symptoms and with no signs but mild elevations of blood pressure usually require only supportive psychotherapy to prevent a hypertension neurosis

CHOICE OF THERAPY

The multiplicity of therapies indicates that none is ideal and that there is no general agreement on their use However, *each has* some value, and when they are properly used, often in combination, they can modify favorably many of the unfortunate *sequelae* of hypertension. Current therapy includes (1) psychotherapy, (2) diet, (3) drugs, (4) surgery.

PSYCHOTHERAPY[1]

Much of the effect on symptoms and blood pressure level formerly attributed to drugs, diet, and surgery is due to *the psychodynamics* of the doctor-patient relationship. When this relationship is wisely used by the physi-

[1] The psychologic aspects of hypertension have been discussed in Chap 2. *Editor.*

Treatment of the hypertensive states

EDWARD MEILMAN

The remarkable variety of potent hypotensive drugs and measures now available has placed new responsibilities on the physician caring for patients with hypertensive cardiovascular disease. Less than a generation ago, the medical armamentarium consisted of sedatives (such as barbiturates and bromides), vasodilators (such as nitrites and xanthines), thiocyanates, and reassurance The real advantages and the technique of stringent salt restriction proposed by Allen (1920) did not have wide recognition In fact, diet was recommended only for obesity Removal of portions of the sympathetic nervous system had begun The still unsolved problem of suitable case selection appeared early in the history of this operation. The action of placebos and other psychotherapeutic measures on blood pressure levels had been clearly delineated, with proper emphasis placed on the relation of home and office blood pressure readings The personality disorders in many patients with hypertension were appreciated, but the concept that emotional stresses could convert hypertension into an accelerated phase was new

At present, a growing list of drugs, various forms of low-salt diet, psychotherapy, and surgery of the adrenal glands and of the sympathetic nervous system require consideration of their proper role in the therapy of hypertensive cardiovascular disease. Except for rare instances of specific kinds of hypertension amenable to surgical cure (coarctation, adrenal tumors, unilateral renal disease), the selection of the proper modality of treatment remains entirely empirical and largely a matter of trial and error. These measures are not simple to select and administer, nor are they successful in every case

Despite marked differences in their mechanism of action, all the measures thus far suggested as therapy in hypertension share in varying degree the ability to lower arterial blood pressure Thus the advisability and results of lowering blood pressure must be examined before the specific therapies themselves

THE EFFECT OF LOWERING BLOOD PRESSURE

For many years, and to some extent today, objections have been raised to hypotensive programs because of evidence that atherosclerosis can progress and kill despite lowered blood pressure, and belief that the process is neither ameliorated nor delayed by lowering the blood pressure Moreover, it has been claimed that lowering blood pressure may deprive the tissues beyond constricted or organically narrowed arterioles of adequate nourishment For example, coronary disease may progress following a sympathectomy; falls in blood pressure, especially when sudden and severe, and accompanied by shunting of large volumes of blood into venous areas, may precipitate precordial pain and even myocardial infarction, as well as cerebral thrombosis and infarction There is, however, a growing body of clinical and laboratory evidence indicating that the elevated blood pressure itself is a ma-

its effectiveness in restoring vision will give some patients the motivation to remain on it for long periods For most patients, the greatest usefulness of the rice diet is to promote acceptance of a 200-mg-sodium diet. It is now well recognized that the effectiveness of the rice diet depends on its low sodium content. As long as the daily sodium intake is 500 mg or less, about one-fourth of the patients may be expected to have a favorable response. Raising the daily intake above 500 mg usually results in a rise of blood pressure Measurement of 24-hr excretion of sodium is important in differentiating blood pressure fall from diet versus blood pressure fall in response to the psychic effects of a somewhat bizarre program At present, there seems to be no clear advantage of the rice diet over a 200-mg-sodium diet. In either case, and especially in the presence of renal disease, determination of the electrolytes in the blood should be carried out at intervals to observe whether low serum sodium and nitrogen retention are occurring Mercurials, carbonic anhydrase inhibitors (Diamox), ammonium chloride, and cation-exchange resins have been recommended as adjuncts to sodium restriction Although these measures may mitigate some of the harshness of a 200-mg-sodium diet, they do not allow the patient to eat normally. Resins introduce other problems, since they cannot remove sodium selectively. Losses of potassium, calcium, and magnesium occur, together with metabolic acidosis

For patients with heart failure, malignant hypertension, or even uncomplicated hypertension, sodium restriction alone is often effective This program is worth following only in patients with severe degrees of hypertension or with evidence of vascular disease, such as grade III or IV eye grounds, enlarged heart with congestive failure or coronary artery disease, or early renal disease. The only contraindication is a significant degree of renal failure

DRUGS

The need for a suitable oral preparation for the control of elevated blood pressure has led to a revival of interest in old drugs as well as search for new, synthetic ones. Some drugs stimulate the afferent side of reflex vasodepressor mechanisms (the *veratrum* esters); some inhibit sympathetic activity centrally (dihydrogenated *ergot* alkaloids); some act centrally and also peripherally, probably against circulating pressor agents (*hydrazinophthalazine*); some act on efferent pathways by paralyzing cholinergic transmission at autonomic ganglia (*ganglionic blocking* agents) or act directly on the smooth muscle of the arterioles to prevent the usual response to circulating sympathetic pressors (*dibenamine* compounds); some have not only a central, hypothalamic action but a complex effect on other tissues (*rauwolfia* derivatives).

Rauwolfia serpentina. The newest and most intriguing of the hypotensive drugs comes from *Rauwolfia serpentina*. This drug has been used in India primarily for its psychiatric sedative effects on disturbed persons. In 1942 its moderate hypotensive properties were described by Indian workers, and in 1953 Wilkins introduced this drug into the United States. Since then, it has had extensive trial in hypertension and in many psychiatric conditions. The crude root, standardized alkaloidal extracts, and the pure alkaloids (*reserpine, rescinnamine, deserpidine*) seem to have similar pharmacologic properties It has been suggested that the pure alkaloids vary in their production of disagreeable side effects, notably depression. An almost flat dose-response (blood pressure) curve, unique among present hypotensive drugs, indicates that rauwolfia has a remarkable degree of safety. Adults and even children who have ingested large amounts of the drug have suffered only from excessive sedation, diarrhea, and moderate hypotension.

Rauwolfia acts on the central nervous system, presumably at the hypothalamus, and its ability to decrease heart rate and blood pressure suggests either an inhibition of sympathetic or an enhancement of parasympathetic activity. However, orthostatic hypotension occurs only rarely with rauwolfia Pupillary constriction and relaxation of the nictitating membrane are characteristic in animals, in man, nasal stuffiness is common, often resulting in symptoms of a chronic cold, bloody nasal discharge, and even sinusitis and otitis. Additional evidence of parasympathomimetic activity is the increased secretion of hydrochloric acid in the stomach, with obvious implications for patients with peptic ulcer. Increased intestinal motility may result in diarrhea. In ani-

mals, rauwolfia interferes with the reflex blood pressure rise, mediated by the central nervous system, that is the normal response to hypoxia or carotid sinus occlusion. A characteristic effect of these drugs is a decrease in motor activity (animals) and an unusual placidity (man). The sedation induced by rauwolfia has been aptly labeled *tranquillity*, but this passes readily from calmness and languor to severe depression. *Depression* is common with excessive doses, but it has occurred even with doses in the usual clinical range. In mild form, it appears as a lack of initiative or creativeness. In fact the occurrence of depression has been the most serious side effect of these drugs; they are obviously contraindicated if depression already exists Depression is said to be less common with *deserpidine*. The drug-induced depression usually responds after some weeks to withdrawal of the drug, if electric shock therapy is contemplated, at least one week and preferably more should elapse after discontinuing the drug because it lowers the convulsive threshold. Violent nightmares may occur; in the author's experience, some patients have fewer of these on *rescinnamine* than on *reserpine* Partial or total loss of libido in the male is a common problem A few cases resembling paralysis agitans have been noted in association with rauwolfia, as well as with other tranquilizers such as chlorpromazine. Weight gain is common, and in some cases of heart failure has been said to be associated with worsening of the edema

At the molecular level, reserpine appears to be able to displace serotonin, norepinephrine, and probably epinephrine from intracellular binding sites in the brain tissues, the gastrointestinal tract, the platelets, and even the heart. Administration of reserpine to animals causes an increased urinary excretion of 5-hydroxyindoleacetic acid, a metabolite of serotonin. This has naturally suggested that the pharmacologic properties of the drug are due to the release of serotonin. However the demonstration that norepinephrine is also released suggests that the loss of these constrictor agents from the body [illegible] he vascular system from their effec[illegible]

Emphasis on the side [illegible] lfia should not detract fr[illegible] remarkable therapeutic [illegible] and moderate hyp[illegible] claimed to be [illegible]

tensive patients with labile blood pressure, anxiety, tachycardia, and no evidence of vascular disease. Yet, there is often a satisfying response of blood pressure and symptoms of headache, dizziness, insomnia, and nervousness in older persons with "fixed" hypertension associated with evidence of vascular disease.

DOSAGE Orally, the pure alkaloids are given in daily doses of 0.25 to 1.0 mg for 7 to 10 days, after which the daily dose is reduced to 0.1 to 0 25 mg, depending on the response. Parenteral administration (1 to 2 5 mg intravenously or intramuscularly) has the same general effects as the oral, causing sedation and a moderate blood pressure fall lasting about 6 hr. Curiously, in some individuals it may take several weeks for the full hypotensive effect to appear, when the drug is discontinued, its effects may last 1 to 4 weeks, even though the administered drug appears to be excreted in several hours Undesirable side effects are often controlled by omitting the drug for 1 week out of 4 The hypotensive effect can be successfully overcome by ephedrine or phenylephrine Synergistic effects with other hypotensive drugs are difficult to prove, but the bradycardia of rauwolfia tends to overcome the tachycardia of hydralazine, its bowel-stimulating action may mitigate the constipation from ganglionic blocking drugs, and its tranquilizing effects may make veratrum effective with less vomiting Thus, smaller doses of the other drugs can usually be used if rauwolfia is also employed Rauwolfia and its pure alkaloids therefore seem to be worthwhile in early, mild cases if nervousness and tachycardia are prominent, and simple barbiturate sedation or psychotherapy ineffective. In more severe cases with headache, dizziness, or other evidence of hypertensive cardiovascular disease, it may be useful alone but more likely in combination with other drugs The most serious side effect is depression

The Veratrum Alkaloids [Veriloid, Unitenson, Protoveratrine (Veralba)] Medicinal properties have been known for centuries to reside in the *Veratrum* plants Recently, attention has been directed anew to hypotensive properties of pure ester alkaloids as well as crude extracts of the roots. The side effects, as well as the hypotensive action of crude root, biologically standardized extract, or purified esters such as *protoveratrine A and B*, are [illegible]ar However, the narrow [illegible]nge between

therapeutic and toxic doses, characteristic of these drugs, *favors* the use of crystalline substances. The pharmacologic action of these agents has shown the existence of a reflex decrease in heart rate and blood pressure due to afferent stimulation of chemoreceptors in the heart and great vessels (*the Bezold-Jarisch reflex*). The veratrum esters cause a veratrinic response (repetitive electric discharges from a single stimulus) in the chemoreceptors of the carotid sinus, aortic arch, and coronary vessels of the left ventricle. This increase in afferent electrical activity travels over the vagus and carotid sinus nerves to the vasomotor center in the brain, which then causes a diminution in efferent electrical discharges over the splanchnic and presumably other sympathetic nerves, resulting in a generalized vasodilatation and a fall in blood pressure. This vasodilatation is accompanied by a decrease in cerebrovascular and renal resistance. The veratrum alkaloids also block the carotid sinus pressor reflex and may have some direct central nervous system hypotensive action. In cats, it has been shown that *stimulation of the nodose* ganglion is the source of the vomiting reflex. The hypotension is usually accompanied by bradycardia due to a simultaneous reflex increase in vagal activity.

Toxic doses in man cause epigastric and substernal oppression, nausea, vomiting, sweating, severe hypotension, bradycardia, and even *heart block*. The disturbances of heart rate *and* rhythm are vagal phenomena and are blocked by *atropine* (0.5 to 1.0 mg subcutaneously or intravenously) without, as a rule, eliminating the hypotension. Severe hypotension *is* readily overcome by *ephedrine sulfate* (25 to 35 mg subcutaneously) or *other vasoconstrictor drugs*. *Cardiac irregularities are* more likely *in* patients receiving *digitalis* or *quinidine*. At the peak hypotensive effect, there may be transient electrocardiographic changes *such as* T-wave inversion in leads V_3 to V_4. These are reversed by *atropine* but *not by oxygen*, indicating that they also are *reflex* vagal phenomena. The importance *of distinguishing* a toxic *reaction to* veratrum from a myocardial infarction *is apparent*. Severe vomiting *can* be moderated or overcome by *barbiturates* or chlorpromazine. Since there is no *paralysis* of autonomic activity, interference with *postural* reflexes and the cold-*pressor* response *does* not occur. However, *if* severe hypotension has ensued, standing may cause a further fall in blood pressure. *Oliguria* and diminished glomerular filtration rate may occur during hypotension from veratrum drugs, resembling those seen after any sudden fall in systemic pressure, but they are transitory even if the hypotension is maintained. Fluid retention does not occur. *In fact, negative fluid* and sodium balance can be seen in women with toxemia of pregnancy while under continuous treatment with *veratrum*. *The renal* vasodilatation which occurs with veratrum is not associated with increased cardiac output. In some patients with nitrogen retention, cautious lowering of the blood pressure may be achieved with little or no aggravation of the *renal status. In others*, *especially* when uremia is present, veratrum, like other hypotensive agents, will aggravate the renal *insufficiency*. Nonetheless, even in this *group*, *control* of *encephalopathy*, headache, diminishing vision, and heart failure *may be obtained*.

Administered parenterally, the veratrum alkaloids are probably the drugs of choice when prompt *predictable fall in* blood pressure without *rise in* cardiac output or *disturbance of homeostatic* reflexes is desired. *They are virtually* specific for acute hypertensive encephalopathies, the hypertension *and convulsions* of toxemia of pregnancy, *pulmonary* edema occurring in acute glomerulonephritis, and *steroid*-induced hypertension. These *drugs may* be useful in the treatment of *hypertensive pulmonary edema* if conventional *methods fail*. They are *very useful in malignant* hypertension, especially when loss of *vision is* threatened. Of 9 patients with *malignant* hypertension treated with *parenteral protoveratrine*, 5 *had remissions* and were alive 3 to 5 *years later*. Patients with congestive *heart failure* or coronary disease associated *with hypertension* who show a satisfactory *response to* veratrum, alone or combined with *reserpine*, may expect alleviation *of* failure and decrease in angina.

The intravenous dosage of protoveratrine *A and B* is 1.5 to 1.9 µg/kg, with subsequent *doses* of 20 µg at 10-min intervals until a *satisfactory* hypotensive effect is obtained. The hypotension can be maintained for hours by continuous intravenous *infusion* at the rate of about 1 µg/min. The *duration of action* of a single effective *intravenous injection* (average dose 100 µg) is 1 *to* 3 *hr*. Subcutaneous or

mals, rauwolfia interferes with the reflex blood pressure rise, mediated by the central nervous system, that is the normal response to hypoxia or carotid sinus occlusion. A characteristic effect of these drugs is a decrease in motor activity (animals) and an unusual placidity (man). The sedation induced by rauwolfia has been aptly labeled *tranquillity*, but this passes readily from calmness and languor to severe depression. *Depression* is common with excessive doses, but it has occurred even with doses in the usual clinical range In mild form, it appears as a lack of initiative or creativeness. In fact the occurrence of depression has been the most serious side effect of these drugs, they are obviously contraindicated if depression already exists. Depression is said to be less common with *deserpidine* The drug-induced depression usually responds after some weeks to withdrawal of the drug, if electric shock therapy is contemplated, at least one week and preferably more should elapse after discontinuing the drug because it lowers the convulsive threshold. Violent nightmares may occur; in the author's experience, some patients have fewer of these on *rescinnamine* than on *reserpine* Partial or total loss of libido in the male is a common problem. A few cases resembling paralysis agitans have been noted in association with rauwolfia, as well as with other tranquilizers such as chlorpromazine. Weight gain is common, and in some cases of heart failure has been said to be associated with worsening of the edema

At the molecular level, reserpine appears to be able to displace serotonin, norepinephrine, and probably epinephrine from intracellular binding sites in the brain tissues, the gastrointestinal tract, the platelets, and even the heart. Administration of reserpine to animals causes an increased urinary excretion of 5-hydroxyindoleacetic acid, a metabolite of serotonin. This has naturally suggested that the pharmacologic properties of the drug are due to the release of serotonin However, the demonstration that norepinephrine is also released suggests that the loss of these constrictor agents from the body spares the vascular system from their effects.

Emphasis on the side actions of rauwolfia should not detract from the use of these remarkable therapeutic agents for sedation and moderate hypotension. The drugs have been claimed to be most effective in young hypertensive patients with labile blood pressu anxiety, tachycardia, and no evidence of v cular disease. Yet, there is often a satisfyi response of blood pressure and symptoms headache, dizziness, insomnia, and nervo ness in older persons with "fixed" hypertens associated with evidence of vascular disea

DOSAGE. Orally, the pure alkaloids are gi in daily doses of 0 25 to 1.0 mg for 7 to days, after which the daily dose is reduced 0.1 to 0.25 mg, depending on the respon Parenteral administration (1 to 2.5 mg int venously or intramuscularly) has the same g eral effects as the oral, causing sedation an moderate blood pressure fall lasting about 6 Curiously, in some individuals it may take s eral weeks for the full hypotensive effect to pear; when the drug is discontinued, its eff may last 1 to 4 weeks, even though the adm istered drug appears to be excreted in sev hours Undesirable side effects are often c trolled by omitting the drug for 1 week of 4. The hypotensive effect can be succ fully overcome by ephedrine or phenylephr Synergistic effects with other hypoten drugs are difficult to prove, but the brady dia of rauwolfia tends to overcome the tac cardia of hydralazine, its bowel-stimulating tion may mitigate the constipation from gan onic blocking drugs, and its tranquilizing fects may make veratrum effective with vomiting Thus, smaller doses of the o drugs can usually be used if rauwolfia is employed Rauwolfia and its pure alkal therefore seem to be worthwhile in early, r cases if nervousness and tachycardia are pro nent, and simple barbiturate sedation or p chotherapy ineffective In more severe c with headache, dizziness, or other evidenc hypertensive cardiovascular disease, it may useful alone but more likely in combina with other drugs. The most serious side ef is depression

The Veratrum Alkaloids [Veriloid, Uni son, Protoveratrine (Veralba)] Medic properties have been known for centuries reside in the *Veratrum plants* Recently, at tion has been directed anew to hypoten properties of pure ester alkaloids as well crude extracts of the roots The *side effects* well as the hypotensive action of crude r biologically standardized extract, or puri esters, such as *protoveratrine A and B*, similar. However, the narrow range betw

synthetic agent were first described in 1950. *Hydralazine* is an orally effective drug which appears to act on the central nervous system as well as peripherally, where it neutralizes the effects of a number of circulating vasopressor agents. In animals, sympatholytic activity is demonstrable, with the doses used in man, these effects are minimal. Although an increase in renal blood flow accompanies the moderate fall in systolic and diastolic pressure, this drug is not more effective in renal hypertension than in other varieties. It does not increase glomerular filtration rate and does not elevate to normal the depressed renal blood flow of essential hypertension. A direct stimulating effect on the heart results in tachycardia and increased cardiac output, which explains the aggravation of precordial pain and of congestive heart failure which has sometimes occurred even when blood pressure was lowered by this drug. Hydralazine may improve the contours of the ballistocardiogram, presumably because of peripheral vasodilatation, however, the electrocardiogram in patients with coronary disease may show changes of hypoxia after hydralazine. For these reasons, *rauwolfia* or *veratrum* should be used to slow the heart rate and lower the blood pressure before hydralazine is given to patients with coronary artery disease or congestive failure. Similarly, if the pressure is first lowered with a ganglionic blocking drug, hydralazine can then be given cautiously to such patients.

Toxic symptoms include nausea, vomiting, some degree of postural hypotension, and headache. The latter may be quite severe but can usually be minimized if treatment is begun with small doses. Prolonged administration of the drug has resulted in fever, edema, rashes, and a new type of disorder resembling certain collagen diseases. As many as 10 per cent of patients who receive this drug in large doses and for more than one year develop some or all of the syndrome. Fully developed, it includes arthritis, rash, fever, anemia, hematuria, lymphadenopathy and splenomegaly, albuminuria, positive cephalin flocculation, and even lupus erythematosus cells. This syndrome has appeared primarily in patients receiving large doses (over 500 mg daily) and in whom the blood pressure was successfully lowered. Thus far the disturbance has remitted when hydralazine was stopped, and in some cases corticotropin given. Rarely hydralazine has been observed to cause acute psychotic reactions.

Initial dose should be 25 mg or less, four times daily. Increments of 25 mg per dose are added every 3 to 4 days unless severe headache appears. Daily doses have ranged as high as 500 to 600 mg a day, but in view of the high incidence of drug toxicity, it is doubtful whether more than 400 mg a day should be given. Prolonged administration of hydralazine alone is accompanied not only by a rising incidence of drug toxicity but also by a diminution in the number of good responses. Initially, satisfactory hypotension is obtained in about one-third of the patients, but after 1 to 2 years of treatment the percentage of patients showing good results has diminished to one-tenth. Milder forms of hypertensive disease may respond to small doses of *hydralazine*, especially in conjunction with *rauwolfia* or *veratrum*, without a high incidence of toxic reactions. In general, large doses of hydralazine should be reserved for patients with severe forms of hypertensive disease in whom other treatment is inadequate. In conjunction with *hexamethonium*, however, it has been a very effective agent in severe forms of hypertensive disease.

Ganglionic Blocking Drugs. The demonstration that *tetraethylammonium* ion could block cholinergic transmission at autonomic ganglia has led to extensive pharmacologic study of quaternary ammonium compounds as therapeutic agents in hypertension. The most widely studied and the first to be shown to have clinical usefulness was *hexamethonium* $[(CH_3)_3\text{-}N^+(CH_2)_6N^+(CH_3)_3]$. Since then salts of *pentolinium* [illegible] chlorisondamine chloride], and *mecamylamine* (*3-methylaminoisocamphane*) have received clinical trial. All have qualitatively the same pharmacologic properties, but pentolinium has a somewhat longer duration of action than hexamethonium, and mecamylamine and chlorisondamine have a still longer duration. Mecamylamine has the further advantage of virtually total absorption from the gastrointestinal tract.

The ganglionic blocking drugs act by partial or total block at ganglionic synapses without interfering with pre- or postganglionic

intramuscular doses of 4 to 6 μg/kg at 6- to 8-hr intervals will give 3 to 8 hr of lowered blood pressure. The incidence of nausea and vomiting tends to increase after several weeks of therapy.

Oral administration of pure, as well as crude veratrum drugs, causes a high incidence of nausea and vomiting, which seriously limits the use of this drug in chronic hypertension However, in some patients the drug may be given for years without loss of blood pressure response and only occasional episodes of nausea and vomiting Usually three or four daily doses, i.e., after breakfast, about 2 P.M., after supper, and at bedtime can be tolerated The individual doses start at 0 25 mg, with increments of 0 125 mg each dose until toxic effects or satisfactory blood pressure levels are reached. Hoobler has recommended a single large dose (0 5 to 1 5 mg) after breakfast followed by two doses of 0.25 mg at 2- to 3-hr intervals, a similar program begun after supper has been useful in controlling nocturnal dyspnea Studies of *protoveratrine* A and *B* have suggested that B is less toxic when given orally, even though both have similar effects parenterally.

Despite the dramatic nature of the toxic effects and occasional severe hypotension, no deaths have been reported from the use of veratrum It is still probably the best drug for parenteral administration in the short-term therapy of acute hypertensive states Used orally, it is best combined with rauwolfia Its mechanism of action would make it an ideal hypotensive agent were it not for its tendency to provoke vomiting

Dihydrogenated Ergot Alkaloids. In 1943 the hydrogenation of *ergot* alkaloids was found to yield substances with considerable sympatholytic activity but with little or no vasoconstrictor action The sympatholytic activity of 0.2 to 1 0 mg of *dihydroergocornine (DHO)* given intravenously or intramuscularly produces not only orthostatic hypotension but a fall in supine blood pressure of variable degree and bradycardia. Nasal stuffiness, fatigue, nausea, and vomiting are common DHO inhibits reflex vasoconstriction (cold-pressor test, Valsalva overshoot). The hypotensive effect lasts from 1 to 24 hr. Oral administration requires 4 to 10 mg, and hypotensive action is erratic or absent. Vomiting is induced in one-fourth of the patients even in the absence of hypotension. In these respects, oral administration recalls the difficulties with veratrum In one study of 17 patients who received *Hydergine* parenterally for 3 to 6 months, 12 showed significant blood pressure falls and 1 showed clearing of papilledema. Curiously enough, Hydergine prevents the development of audiogenic hypertension in rats.

Dibenamine Compounds. A number of *β-halo-alkylamines* cause a peripheral adrenergic blockade which lowers blood pressure in a considerable number of patients with essential and malignant hypertension. *Dibenamine,* the prototype of this series, must be given intravenously, slowly and diluted. A dose of 5 mg/kg intravenously will cause an orthostatic hypotension that may last from 5 to 6 days The fall in supine blood pressure, if any, will last from a few hours to over 24 hr. The pupils constrict and the nose is congested The skin temperature rises. There are generalized peripheral vasodilatation and increased stroke volume of the heart. Dibenamine occasionally has marked excitatory effects on the central nervous system (confusion, restlessness, and, rarely, transient psychosis), as well as causing drowsiness, nausea, and vomiting Following dibenamine, administration of *epinephrine* no longer causes a rise in blood pressure; in some cases, it may even cause a fall (epinephrine reversal) However, the characteristic epinephrine tachycardia is not inhibited. In fact, it may be exaggerated because there is no blood pressure rise and hence no reflex cardiac slowing

An orally effective dibenamine congener (*Dibenzyline*, N-phenoxyisopropyl-N-benzyl-β-chloroethylamine hydrochloride) has been studied as a therapeutic agent. The duration of effect from one dose of Dibenzyline is 3 to 4 hr, and there are several reports of its usefulness as a hypotensive agent in a proprietary mixture also containing *protoveratrine* and *rauwolfia* Three daily doses are necessary, and the drug must be titrated to obtain the desired effect Blood pressure response may not occur for 3 to 4 weeks; when the drug is omitted, the pressure returns slowly to its previous levels. The side effects are manifestations of adrenergic blockade.

Hydralazine (1-Hydrazinophthalazine, Apresoline). The hypotensive properties of this

synthetic agent were first described in 1950. *Hydralazine* is an orally effective drug which appears to act on the central nervous system as well as peripherally, where it neutralizes the effects of a number of circulating vasopressor agents In animals, sympatholytic activity is demonstrable, with the doses used in man, these effects are minimal Although an increase in renal blood flow accompanies the moderate fall in systolic and diastolic pressure, this drug is not more effective in renal hypertension than in other varieties. It does not increase glomerular filtration rate and does not elevate to normal the depressed renal blood flow of essential hypertension. A direct stimulating effect on the heart results in tachycardia and increased cardiac output, which explains the aggravation of precordial pain and of congestive heart failure which has sometimes occurred even when blood pressure was lowered by this drug Hydralazine may improve the contours of the ballistocardiogram, presumably because of peripheral vasodilatation, however, the electrocardiogram in patients with coronary disease may show changes of hypoxia after hydralazine For these reasons, *rauwolfia* or *veratrum* should be used to slow the heart rate and lower the blood pressure before hydralazine is given to patients with coronary artery disease or congestive failure. Similarly, if the pressure is first lowered with a ganglionic blocking drug, hydralazine can then be given cautiously to such patients.

Toxic symptoms include nausea, vomiting, some degree of postural hypotension, and headache. The latter may be quite severe but can usually be minimized if treatment is begun with small doses Prolonged administration of the drug has resulted in fever, edema, rashes, and *a new type of disorder resembling certain collagen* diseases As many as 10 per cent of patients who receive this drug in large doses and for more than one year develop some or all of the syndrome Fully developed, it includes arthritis, rash, fever, anemia, hematuria, lymphadenopathy and splenomegaly, albuminuria, positive cephalin flocculation, and even lupus erythematosus cells Thus syndrome has appeared primarily in patients receiving large doses (over 500 mg daily) and in whom the blood pressure was successfully lowered Thus far the disturbance has remitted when hydralazine was stopped, and in some cases corticotropin given. Rarely hydralazine has been observed to cause acute psychotic reactions

Initial dose should be 25 mg or less, four times daily. Increments of 25 mg per dose are added every 3 to 4 days unless severe headache appears. The side effects are manifestations of adrenergic blockade

Hydralazine (1-Hydrazinophthalazine, Apresoline). The hypotensive properties of this

theoretically less of a problem However, some instances of central nervous system disturbance, tremors, and hallucinations, usually in very sick patients, have been attributed to it.

Dosage for each patient is a matter of trial. Pentolinium is administered in doses of 20 mg (of the bitartrate salt) after breakfast, in midafternoon, and at bedtime. Increments of 20 mg are made slowly every few days until either satisfactory blood pressure response (not lower than 120 mm Hg systolic in the erect position) or uncontrollable toxic effect appears Mecamylamine is begun in doses of 2.5 mg—in three daily doses, as with pentolinium Increments are 2.5 mg Ecolid is begun in two daily doses of 50 mg each, with increments of 25 to 50 mg every few days.

Many investigators, following Ayman's suggestion, recommend home blood pressure readings, to obviate the notoriously unreliable "office" reading, and adjustment of medication dosage on the basis of home blood pressures[2] Some believe that transient dizziness in the erect position is a satisfactory end point. In general, smaller doses are required for patients who are active than for those in bed. Alcohol, vigorous exercise, hot weather, a large meal, low-salt diet, previous sympathectomy, all tend to potentiate orthostatic hypotension. Education of the patient to understand the effects and side effects of these drugs is essential to good management

Contraindications to ganglionic blocking drugs include (1) generalized and, especially, advanced cerebral arteriosclerosis, (2) prostatic symptoms, (3) recent (6 to 12 weeks) coronary or cerebral thrombosis, (4) pyloric stenosis, (5) uremia, and (6) noncooperation by the patient Recently Schroeder has pointed out that some patients with moderate degrees of nitrogen retention can be successfully treated. Although nitrogen retention may increase during the early period of therapy, persistence may result in a subsequent fall of the blood urea level Therapy with ganglionic blocking drugs is indicated in patients with the malignant phase of hypertension, with congestive failure or other evidence of severe hypertensive disease, preferably with rauwolfia and hydralazine, if simpler measures have been ineffective Any patient recommended for sympathectomy should have prior therapy with ganglionic blockers.

[2] The entire dose is taken if the standing systolic pressure is 140 or over, two-thirds is taken for systolic pressure between 120 and 140, the dose is omitted if the systolic pressure is under 120 mm Hg.

Choice of Drug Combinations. The empirical nature of therapy in hypertensive cardiovascular disease has naturally led to the use of several drugs or measures in combination. The undesirable effects of some of the drugs are mitigated by the smaller doses necessary and because some of the side effects tend to overcome each other (such as bowel disturbance with ganglionic block and rauwolfia). However, combinations leave the patient vulnerable to additional toxic reactions The more potent drugs seem to be more toxic, but serious side effects may appear with any of them

Reassurance, supportive *psychotherapy*, and *reorientation* to the stresses of life are usually all that is necessary for the patients with mild, early, asymptomatic hypertension and no evidence of vascular disease, and for those whose hypertension has proved benign by its long duration (especially elderly persons with only moderate degrees of left ventricular enlargement). *Phenobarbital* may be helpful in this group *Rauwolfia*, especially if used intermittently with close observation for side effects, may be useful in these patients if they are very tense Hypotensive agents should be given to patients with sustained high diastolic pressure, especially men, and to patients with evidence of progressive, but not malignant, hypertensive disease. Initial therapy should include *rauwolfia* or *low-sodium diet*. If there is no response in 2 to 3 months, *veratrum* (or *protoveratrine*) may be tried Later, if the disease remains uncontrolled, this group may require *ganglionic blocking drugs*. Patients with hypertensive cerebrovascular disease may be given *rauwolfia, low-sodium diet, veratrum*, or small doses of *hydralazine* in that order. Hypertension and coronary artery disease may be treated with *rauwolfia, low-sodium diet*, and *veratrum* *Ganglionic blocking drugs* cautiously administered to lower pressure slowly and not too far, with the later addition of small doses of *hydralazine*, occasionally give remarkable relief of angina If congestive failure or the malignant phase unresponsive to salt restriction or veratrum appears, *ganglionic blocking drugs* must be given. For acute hypertensive crisis,

function. The end organs of both the parasympathetic and the sympathetic system remain responsive to the appropriate chemical stimulus, or to a postganglionic electrical stimulus. For example, arterioles, unresponsive to preganglionic stimulation after ganglionic blockade, will constrict to norepinephrine; the salivary gland, unresponsive to the stimulus of food, will secrete if a cholinergic drug is given, similarly, the lax bowel will constrict with Prostigmine or other cholinergic agents.

In general, the effects of these drugs are those to be expected from a blockade of autonomic ganglia. Most patients, even normotensive persons, show *orthostatic hypotension* and *compensatory tachycardia* after administration of ganglionic blocking drugs Blood pools in the legs and splanchnic region unopposed by reflex sympathetic vasoconstriction of arterioles and veins. When severe, this may lead to *faintness* or even *collapse* If the patient sits or lies flat, such symptoms should abate. Since the aim of treatment is to achieve *some* degree of postural hypotension, this cannot be considered a side effect In some instances, there is even decline of the supine blood pressure The venous pressure falls in normal persons as well as in those with congestive failure If the subject is immersed in a swimming pool, the external pressure of the water replaces sympathetic vasoconstriction of venous channels and hence the hypotension and tachycardia are completely counteracted

As with other hypotensive agents, the hypotension produced by ganglionic blocking drugs does not materially interfere with adequate renal function, but poor renal function is apt to be adversely affected Interference with sympathetic nervous activity causes an increased susceptibility to other stresses Less anesthesia is required for patients under ganglionic block; hypoglycemia may progress quietly into coma without eliciting any of the epinephrine-like reaction characteristic of hypoglycemia in the normal person In warm weather, body temperature rises because of inhibition of sweating, in cold weather, the patient shivers because of lack of reflex skin vasoconstriction Impotence is common but yields to omission of the medication.

Parasympathetic activity is also blocked by these drugs, causing additional undesirable side effects. There is interference with the pupillary reactions to light and accommodation, causing intolerance to bright sunlight and blurred vision. Decreased salivation causes dryness of the mouth. Secretion of hydrochloric acid by the stomach, in the resting state and after insulin, is inhibited, and both stomach and small intestine empty more slowly. The gastric effects of the drug are less pronounced if the stomach is full Although nausea is fairly common, diarrhea is rare Decrease in intestinal motility causes constipation and, in some cases, even ileus. Urinary retention in the male with prostatic hypertrophy may be a problem. Since the oral dose is so much larger than the parenteral one (except for mecamylamine), constipation favors excessive absorption of the drug from the gut and toxic reactions such as paralytic ileus or profound hypotension. Daily bowel evacuation is very important. Deaths have been reported from paralytic ileus as well as from cerebral or coronary thrombosis secondary to severe hypotension. The important differential diagnosis between paralytic ileus and mesenteric thrombosis can be made by noting loss of the pupillary reaction to light and dryness of the skin despite severe hypotension. The side effects due to interference with parasympathetic activity are remedied by oral cholinergic drugs such as *pilocarpine* (5 mg), *Prostigmine* (15 to 30 mg), and urethan of β-methylcholine (*Urecholine*) (5 to 20 mg).

Fatal pulmonary fibrosis has been reported in a small number of patients who received large doses of hexamethonium. These were very sick individuals, many of them in the malignant phase, who also received hydralazine This complication, which appears to be more common in the Negro, has not been reported with other ganglionic blocking drugs. In 9 out of 44 patients with hypertension who died after treatment with hexamethonium or pentolinium, dissecting aneurysm of the aorta was found at post mortem. This high incidence suggests that this also may be an untoward result of therapy

Pentolinium is more potent than hexamethonium on a weight basis and has a longer duration of action, which is its major advantage *Ecolid* has a still longer duration of action and can usually be given in two daily doses *Mecamylamine* is absorbed so well from the gastrointestinal tract that overdosage is

Experimental hypertension

JUAN CARLOS FASCIOLO

PRINCIPLES OF HEMODYNAMICS

The pressure to which the blood is subjected within the arteries depends on the elastic tension of their walls. This tension increases as the elastic fibers are distended, as occurs upon increase of the volume of blood that fills them. The relationship $\frac{\Delta PA}{\Delta VA}$, change in (intra-arterial) pressure (ΔPA) caused by change in (intra-arterial) volume (ΔVA), is a function of the *capacity* and *distensibility* of the arterial system.

The "arterial capacity" may be defined as the volume that fills the arterial system when the internal pressure equals the external pressure. The distensibility may be expressed in terms of arterial "compliance," which could be defined as the change in arterial volume produced by each millimeter of mercury of difference in transarterial pressure,

$$C = \frac{\Delta VA}{\Delta P \text{ mm Hg}}$$

This compliance will be in inverse proportion to the rigidity of the vessels. Changes in the capacity of the arterial system modify the value $\frac{\Delta PA}{\Delta VA}$. If the capacity increases, the value of the relationship decreases, and vice versa. The changes of compliance have the same effect. When the latter increases, the value of $\frac{\Delta PA}{\Delta VA}$ decreases, and when C decreases (i.e., the vessels become more rigid), the value increases. In the arterial system, the capacity and compliance depend upon the characteristics of the larger vessels, especially of the aorta. Therefore the arterial system of a subject in whom the capacity and compliance of the arteries have a constant value should be considered without admitting the possibility that both compliance and capacity may be changed by variations in the tone of smooth muscle present in the walls of the larger arterial vessels. In this case the value of PA will be a function of VA. VA in turn depends on the balance between *the amount of blood entering the system in a certain period of time—Ve (ventricular ejection)—and that amount which leaves the system—Vs.*

$$VA = Vi + (Ve - Vs)$$

where Vi (initial volume) = the volume present before the time in which Ve and Vs are measured.

Ve is dependent upon the venous return and the physiologic status of the heart. Vs depends upon (1) the difference in pressure between the arterial and venous systems; (2) the viscosity of the blood; and (3) the diameter and length of the smaller blood vessels, especially the arterioles. If the last two factors are designated as R, Poiseuille's law states that $PA = Ve \times R$.[1] Poiseuille's law is applied to systems in which viscous fluids circulate without turbulence. It appears that in the arterial system, blood, because of its cellular components, behaves in the smaller vessels as a pseudoplastic fluid, while turbulence seems absent. For this reason, the formula $PA = Ve \times R$, which

[1] The most important formulas pertaining to the cardiovascular system can be found in Part II, Chaps. 6, 14, 15, and 16. *Editor.*

veratrum is the drug of choice. Parenteral *reserpine* may be a useful adjunct. Ganglionic blocking drugs have been used effectively, but are less easily controlled. One-half or more of the patients in the malignant phase of hypertension can now expect reversal if uremia is absent, with various drugs, singly and in combination. The ganglionic blocking drugs are most widely used for this purpose. In this condition particularly, hypotensive medication should not be withdrawn abruptly, lest heart failure, cerebral hemorrhage, or irreversible uremia be precipitated.

SURGERY

The dietary and drug treatment of hypertension is not always effective, and for some severely ill patients it may be necessary to recommend surgery on the sympathetic nervous system or adrenal glands No patient should have surgery without a prior trial of drugs, including ganglionic blockers The popularity of sympathectomy has been declining, even though it was the first procedure clearly to improve the prognosis in malignant hypertension. The application of sympathetic nerve surgery is as empirical as drug treatment, and it is impossible to select the patients destined to do well with operation

The variety of surgical procedures recommended has extended to virtually total sympathectomy, representing formidable and multiple operations, and most surgeons do not believe this offers more benefit than the less extensive procedures. The most widely used operations are those of Peet and of Smithwick. The former is often done in one stage; it does not entail prolonged morbidity from postural hypotension and does not interfere with ejaculation.

The sympathetic chain, from the sixth to the twelfth thoracic nerve, including the splanchnic nerves, is resected on both sides Portions of two ribs must be removed, and the operative mortality is 3 per cent. The Smithwick procedure includes the lumbar ganglia, thus resulting in postural hypotension and interference with potency. This procedure has the advantage of exposing the adrenal glands (to detect a rare instance of pheochromocytoma) as well as the kidneys. Both the Smithwick and Peet procedures may cause severe persistent postoperative neuritis. There is disagreement concerning the necessity of postural hypotension for a good therapeutic response with improvement in survival rates. Lowered blood pressure should persist for a year before the operation can be considered successful.

While the exact role of sympathetic surgery remains unsettled, such operations having been displaced to a large extent by ganglionic blocking drugs, there are a few situations in which operation should be recommended. Any patient with malignant hypertension not responsive to medical treatment within 2 months should have sympathectomy if nitrogen retention is absent. *Surgery is invariably unsuccessful when nitrogen retention is present.* Sympathectomy should be advised for patients with evidence of the rapidly progressive but not necessarily malignant phase of hypertension who cannot be followed very closely, live far from good medical attention, lack the intelligence and cooperation necessary in using the more potent hypotensive drugs, or have not responded to medical treatment Apparently, sympathectomy increases the later effectiveness of drugs and diets.

Adrenalectomy, with or without accompanying splanchnic resection, is still an experimental procedure The good results reported can often be equaled by sympathectomy alone or with sodium restriction In such patients, strict low-sodium intake, with additional measures if necessary to cause negative sodium balance (mercury, resins), and ganglionic blocking drugs would be equally effective. Adrenalectomy is rarely successful unless sufficient adrenal tissue is removed so that the patient requires replacement steroids. Even with total adrenalectomy, some patients show simultaneously high blood pressure and the serum chemical derangements of adrenal insufficiency, not to mention the hazards of cortisone psychosis and metabolic accidents

The variety of empirical medical treatments and the radical nature of the surgery recommended in hypertensive disease indicate that management is far from ideal Difficulties in prognosticating for the individual patient and weighing prognosis against the dangers and discomfort from treatment compound the physician's problem. Yet there is growing agreement that these measures, to be successful, must lower the blood pressure. There is mounting evidence for the suggestion that maintenance of lowered blood pressure will prevent the serious sequelae of this disorder.

sure without changes of the femoral pressure. The increase in carotid pressure is not immediate. If the narrowing is done below the renal arteries, no carotid hypertension occurs. This fact, which has been confirmed in other species, led to the theory which explains the hypertension as the result of renal ischemia caused by the narrowing of the aorta. It has also been shown that compression of the aorta above the renal arteries increases the diastolic pressure, not only in the carotid but also in the femoral arteries. This seems to indicate a generalized vasoconstriction, which in turn could be explained by a humoral mechanism. Nevertheless a mechanical factor also plays a role. This was demonstrated by compressing the thoracic aorta in experiments producing acute arterial hypertension.

On account of the rapid development of collateral circulation, constriction of the aortic arch in the dog does not easily elicit a permanent hypertension (Page, 1940).

Renal Hypertension. It is possible to produce hypertension by altering the renal function by various methods. The degree and duration of the hypertension depend upon the method used, it is often mild and brief. None of the methods described prior to the study of Goldblatt et al. (1934) dealing with incomplete renal ischemia was capable of inducing permanent hypertension with the regularity necessary for systematic study. Most of the methods employed for eliciting renal hypertension are given in the following list

1. Nephrotoxic substances (uranium, bismuth, mercurial and lead salts, oxalates, streptococcic toxins)
2. Nephrotoxic serum
3. Surgical reduction of the renal parenchyma
4. Ligation of the renal arteries or their branches
5. Renal embolism
6. Roentgen irradiation
7. Renal vein occlusion
8. Intermittent occlusion of renal pedicle
9. Occlusion of the ureters
10. Continuous stimulation of the renal nerves
11. Renal compression and perinephritis
12. Total nephrectomy
13. Incomplete renal ischemia
14. Renal lesions caused by choline or potassium deficiency

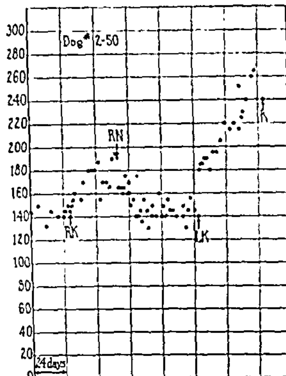

Fig. 12-7. Effect of renal ischemia on the arterial pressure of the dog. Mean arterial pressure in millimeters of mercury. RK, moderate compression of the right renal artery, RN, right nephrectomy; LK, intensive constriction of the left renal artery; K, sacrificed. (From Goldblatt, Ann. Int. Med., 1937.)

Renal Ischemia. The classic experiments of Goldblatt et al. showed that incomplete renal ischemia, secondary to narrowing of the renal artery, is followed in the dog by a permanent elevation of the arterial pressure (Fig. 12-7). These results have been repeatedly confirmed in several other species, such as *Macacus*, rabbit, cat, goat, rat, etc. Goldblatt's original method consisted of placing a silver clamp on the renal artery (Goldblatt clamp), so that the degree of renal ischemia could be regulated.

In the dog, unilateral ischemia (i.e., the other kidney is left intact) is followed by hypertension of 2 to 4 weeks' duration. If the ischemia is bilateral (i.e., if one kidney is ischemic and the other has been removed), the hypertension usually becomes permanent. However, even then, the blood pressure may subsequently decrease and even become normal. This is the result of an increase in collateral circulation; if the new vessels are tied, hypertension again develops.

If the compression is removed from the renal

TABLE 12-4. METHODS EMPLOYED TO PRODUCE ARTERIAL HYPERTENSION

Reduction of the caliber of the aorta	Thoracic aorta or abdominal aorta (above the origin of the renal arteries).
Renal hypertension	Partial or total nephrectomy, renal ischemia, perinephritis; renal vein constriction, etc
Adrenal hypertension	*By means of DOCA* (in the rat) Connected to the sodium content of the diet; potentiated by partial nephrectomy. *By means of cortisone* (in the rat) Sodium is not necessary; potentiated by partial nephrectomy. *By means of aldosterone* Doubtful action *Regeneration of the adrenal cortex* It is necessary to associate reduction of the renal mass and sodium administration
Hypertension by steroids	By vitamin D, corticosterone, methyl-androsternediol, and fluorine derivatives of cortisone (in dogs and rats)
Pituitary hypertension	*By means of somatotropin*, potentiated in the rat by a reduction of the renal mass *By means of ACTH* (in rats) *By thyrotropin* (in the rat), associated with renal mass reduction, the presence of the thyroid is necessary
Thyroid hypertension	*By means of thyroid administration associated with renal mass reduction* (in rats)
Increase of intracranial pressure	Acute and chronic hypertension (in dogs and rats)
Section of the carotid and aortic nerves	Chronic hypertension (in dogs and rabbits)
Cerebral ischemia	Chronic hypertension (in dogs and rabbits)
Semidecortication	Chronic hypertension (in rats)

should be considered as only approximate when applied to the vascular system, is still useful because it makes it possible to deduce the direction of changes that occur in *PA* when *Ve* or *R* is modified.

In most cases of clinical or experimental arterial hypertension, there are no changes in *Ve* nor in viscosity. *Therefore, the increase in pressure is the result of an increase in peripheral resistance.* It is evident that the cause of hypertension should be sought in an increase of tone of the arteriolar muscles, and that knowledge of the humoral, neurogenic, or other factors that modify this tonus will be the key to our knowledge of hypertension.

EXPERIMENTAL PRODUCTION OF ARTERIAL HYPERTENSION

The mechanisms capable of producing arterial hypertension may be conveniently studied by reviewing the different procedures that have been used to produce chronic hypertension in animals. Table 12-4 summarizes the most important methods and some of their characteristics.

Aortic Compression. Narrowing of the thoracic aorta produces an increase in the arterial pressure in the arteries arising above the point of constriction. The narrowing increases the resistance *R* to blood flow; then if the cardiac output remains constant, there is an increase in pressure which is proportional to the resistance ($PA = Ve \times R$).

The aorta has been experimentally narrowed at different levels (Fig. 12-6). Goldblatt et al (1939) showed that in the dog, constriction of the abdominal aorta above the renal arteries causes a permanent increase in carotid pres-

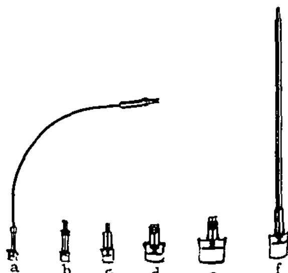

Fig 12-6. Various types of clamps for the compression of aorta or renal arteries. *a*, Clamp with flexible wire for external constriction *b*, *c*, *d*, and *e* Several types of clamps to be left in the animal *f*. Clamp for the constriction of the aorta from the outside. (From Goldblatt. Am J. Clin. Path. 1940)

plasma volume is usually diminished, but normal values may be found, indicating either that the increase of aortic pressure is sufficient to compensate for the narrowing of the renal artery or that the intrarenal resistance has decreased. The filtration is normal and, therefore, there is no nitrogen retention If the blood flow is decreased, the filtration is maintained, because of an increase of the filtration fraction, possibly caused by constriction of the glomerular efferent arteriole. There is no hematuria, proteinuria, or cylindruria, and the concentration and volume of the urine are usually within normal limits.

In this group, the structural changes found in the kidney and cardiovascular system are insignificant. If the hypertension has a certain duration, there is a moderate cardiac hypertrophy, but there are no alterations in the large vessels and the thickness of the aortic wall is normal Usually there is thickening of the muscular layers of the arterioles. The ischemic kidney is normal or shows a slight atrophy of the tubules Alterations of the juxtaglomerular apparatus have been described.

Malignant Hypertension. If both renal arteries (or one renal artery in an animal with only one kidney) are severely constricted, in addition to arterial hypertension, insufficiency of the excretory function of the kidney develops, and retention of urea, nonprotein nitrogen, and creatinine occurs. There is a decrease of the clearance function, and some animals present an acute hypertension, associated with convulsions and retinal detachment produced by retroretinal exudates and hemorrhages Later on, hemorrhagic vomitus and diarrhea may occur On *autopsy, petechiae and hemorrhages* are noted in various organs, especially in the intestines, stomach, and pancreas and serous effusions in the peritoneum and pericardium Microscopically, hyalinization and necrosis of the arteriolar walls are seen. The hyalinization is characterized by deposits of hyaline material in the subendothelial layers, with partial or total obliteration of the lumen. The necrosis may extend through the entire arteriolar wall and cause hemorrhages These arterial lesions seem to be due to the combination of hypertension and renal insufficiency. The areas protected from an increase of pressure by narrowing of the vascular lumen do not exhibit the typical lesions of malignant hypertension (Goldblatt, 1938). In the hypertension of rats caused by daily injection of Doca, carotid ligation prevents the development of cerebral lesions.

The aorta has been experimentally constricted at various levels. Goldblatt et al. (1939) showed that in the dog, constriction of the abdominal aorta above the renal arteries causes a permanent increase of carotid pressure without modification of the femoral pressure. When both carotids are ligated, the protection of the cerebral circulation is complete; it is limited to the homolateral side, when the ligation is unilateral (Robert, 1950).

The possibility of an absorption of autolytic renal proteins has been considered as the cause of vascular lesions.

Protective Action of the Normal Kidney. The increase of blood pressure due to unilateral renal ischemia in the dog is transitory and usually moderate if the other kidney is intact. The extirpation of this kidney is followed by a rapid increase of blood pressure, which then becomes permanent (Fasciolo, 1938). Therefore, it is likely that the normal renal tissue is able to neutralize, within certain limits, the hypertensive effect of the ischemic tissue. The mechanism of this protective effect is unknown. Some investigators think that the hypertrophied normal kidney takes over part of the work that should be done by the ischemic kidney, thus overcoming the metabolic disturbance that causes hypertension. Other data, such as the increased sensitivity to the pressor action of renin, found in nephrectomized animals, suggest a humoral mechanism. The removal of both kidneys in the dog and rat is followed by arterial hypertension if survival is made possible, suggesting a normotensive action of the healthy kidney tissue. This point will be discussed further.

Mechanism of the Hypertension Caused by Renal Ischemia. In the dog made hypertensive by renal ischemia, cardiac output, blood volume, and blood viscosity are normal. For this reason, the arterial hypertension should be attributed to an increase of peripheral resistance The latter is probably secondary to an increase of arteriolar muscular tone. As this tone may be modified by either humoral or neurogenic mechanisms, this form of arterial hypertension may be attributed to either of these mechanisms However, the blood pressure of hypertensive dogs is not normalized, nor is the increased pressure caused by ische-

artery or if the ischemic kidney is removed (in the experiments in which the other kidney is normal), *the arterial pressure again becomes* normal. In other species, such as the rat, unilateral perinephritis may cause a permanent hypertension and the removal of the diseased kidney fails to normalize the arterial pressure (Fig. 12-8). This is apparently because of secondary changes produced in the undamaged kidney by the hypertension.

In arterial hypertension of the dog, produced by renal ischemia, there is an increase of both systolic and diastolic pressures. The heart rate and the cardiac output as well as the blood volume are normal. The degree of alteration of renal function depends on the degree of renal ischemia. If the compression *of the renal arteries is moderate, it is possible* to obtain chronic arterial hypertension without renal insufficiency.

Renal ischemia in the dog may be followed by two types of hypertensive disease: (1) *benign arterial hypertension* without renal or vascular changes, (2) *malignant arterial hypertension* with multiple vascular lesions and renal insufficiency.

Benign Hypertension Induced by Renal Ischemia. When the reduction of the lumen of the renal arteries is moderate, the excretory function of the kidney is not altered. The renal

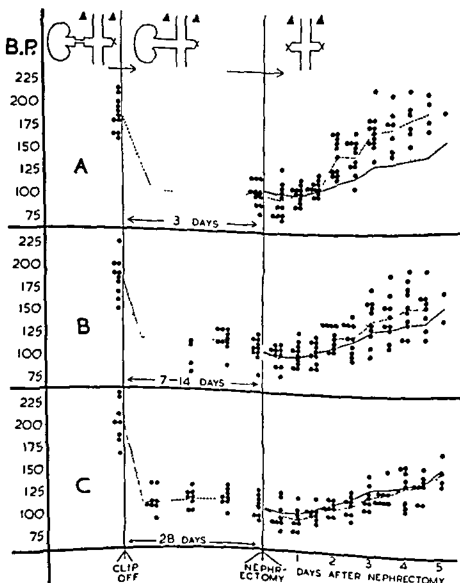

Fig. 12-8. Effect of renal ischemia and of nephrectomy on blood pressure of the rat. A. Nephrectomy at the third day from the elimination of the clip B After 14 days. C. After 28 days. Dotted line, average from ischemic group; full line, average of normal rats after double nephrectomy. (From Floyer. *Clin. Sci.* 1955)

plasma volume is usually diminished, but normal values may be found, indicating either that the increase of aortic pressure is sufficient to compensate for the narrowing of the renal artery or that the intrarenal resistance has decreased. The filtration is normal and, therefore, there is no nitrogen retention. If the blood flow *is decreased*, the filtration is maintained, because of an increase of the filtration fraction, possibly caused by constriction of the glomerular efferent arteriole. There is no hematuria, proteinuria, or cylindruria, and the concentration and volume of the urine are usually within normal limits.

In this group, the structural changes found in the kidney and cardiovascular system are insignificant. If the hypertension has a certain duration, there is a moderate cardiac hypertrophy, but there are no alterations in the large vessels and the thickness of the aortic wall is normal. Usually there is thickening of the muscular layers of the arterioles. The ischemic kidney is normal or shows a slight atrophy of the tubules. Alterations of the juxtaglomerular apparatus have been described.

Malignant Hypertension. If both renal arteries (or one renal artery in an animal with only one kidney) *are severely constricted*, in addition to arterial hypertension, insufficiency of the excretory function of the kidney develops and retention of urea, nonprotein nitrogen, and creatinine occurs. There is a decrease of the clearance function, and some animals present an acute hypertension, associated with convulsions and retinal detachment produced by retroretinal exudates and hemorrhages. Later on, hemorrhagic vomitus and diarrhea may occur. On autopsy, petechiae and hemorrhages are noted in various organs, especially in the intestines, stomach, and pancreas and serous effusions in the peritoneum and pericardium. Microscopically, hyalinization and necrosis of the arteriolar walls are seen. The hyalinization is characterized by deposits of hyaline material in the subendothelial layers, with partial or total obliteration of the lumen. The necrosis may extend through the entire arteriolar wall and cause hemorrhages. These arterial lesions seem to be due to the combination of hypertension and renal insufficiency. The areas protected from an increase of pressure by narrowing of the vascular lumen do not exhibit the typical lesions of malignant hypertension (Goldblatt, 1938). In the hypertension of rats caused by daily injection of Doca, carotid ligation prevents the development of cerebral lesions.

The aorta has been experimentally constricted at various levels. Goldblatt et al. (1939) showed that in the dog, constriction of the abdominal aorta above the renal arteries causes a permanent increase of carotid pressure without modification of the femoral pressure. When both carotids are ligated, the protection of the cerebral circulation is complete; it is limited to the homolateral side, when the ligation is unilateral (Robert, 1950).

The possibility of an absorption of autolytic renal proteins has been considered as the cause of vascular lesions.

Protective Action of the Normal Kidney. The increase of blood pressure due to unilateral renal ischemia in the dog is transitory and usually moderate if the other kidney is intact. The extirpation of this kidney is followed by a rapid increase of blood pressure, which then becomes permanent (Fasciolo, 1938). Therefore, it is likely that the normal renal tissue is able to neutralize, within certain limits, the hypertensive effect of the ischemic tissue. The mechanism of this protective effect is unknown. Some investigators think that the hypertrophied normal kidney takes over part of the work that should be done by the ischemic kidney, thus overcoming the metabolic disturbance that causes hypertension. Other data, such as the increased sensitivity to the pressor action of renin, found in nephrectomized animals, suggest a humoral mechanism. The removal of both kidneys in the dog and rat is followed by arterial hypertension if survival is made possible, suggesting a normotensive action of the healthy kidney tissue. This point will be discussed further.

Mechanism of the Hypertension Caused by Renal Ischemia. In the dog made hypertensive by renal ischemia, cardiac output, blood volume, and blood viscosity are normal. For this reason, the arterial hypertension should be attributed to an increase of peripheral resistance. The latter is probably secondary to an increase of arteriolar muscular tone. As this tone may be modified by either humoral or neurogenic mechanisms, this form of arterial hypertension may be attributed to either of these mechanisms. However, the blood pressure of hypertensive dogs is not normalized, nor is the increased pressure caused by ische-

mia prevented, by renal denervation, sympathectomy, or the destruction of the anterior roots; nor does spinal destruction prevent the increase of pressure. One is therefore inclined to conclude that the increase of arteriolar tone is due to a humoral mechanism.

THE HUMORAL MECHANISM. The arteriolar muscular tone could be stimulated by either an increase of vasopressor or a decrease of vasodepressor substances in the blood. The reactivity of the tissues to vasoactive substances could also be modified, but this modification could only be secondary to changes in the composition of the medium or of the muscle itself (content of sodium, potassium, or other substances). In the last analysis humoral modification would still be involved.

Renal insufficiency and the secondary retention of various metabolites are unable to cause hypertension. Renal ischemia, on the other hand, can elicit hypertension without causing changes of the renal excretory function. Moreover, unilateral renal ischemia is followed by high blood pressure and the removal of the ischemic kidney is rapidly followed by normalization of the blood pressure level. These facts indicate that the vasoconstriction responsible for the hypertension is due to some factor that the ischemic kidney pours into the circulatory system.

RENAL PRESSOR SYSTEM.[2] Tigerstedt and Bergman (1898) showed that the normal kidney contains a hypertensive substance, *renin*. This substance, injected into the blood stream, causes, after a short latent period, an elevation of blood pressure that may persist for 30 to 40 min if large doses are employed. The pressor action is independent of the nervous system and is due to direct action on the arterioles (Fig. 12-9).

Renin is a protein, and its activity is rapidly destroyed by heat over 60°C. It is found in the renal cortex and can be purified by precipitation with ammonium sulfate, sodium chloride, and other chemicals.

The pressor activity of renin is powerful. The most purified preparation has a pressor activity of 470 units per milligram (Haas et al., 1953). A *pressor unit* is the amount of renin that causes an increase of 30 mm Hg in the arterial pressure of a 10-kg dog. Renin has no direct pressor action. It acts on a plasma protein, giving origin to a true pressor substance, *angiotensin*.[3] The plasma protein necessary for the formation of angiotensin has been called "angiotensinogen." It is a protein formed in the liver and is an alpha-$_2$ globulin. Renin acts as an enzyme, angiotensinogen is the substrate. The product of this reaction is a polypeptide with vasoconstrictive action—angiotensin. Applying pepsin on angiotensinogen causes the liberation of a polypeptide which is similar to angiotensin (*Croxatto and Crox-*

[3] Braun-Menéndez, Fasciolo, Leloir, and Muñoz (1939) called the substance formed by the action of renin on the plasma "hypertensin", Page and Helmer (1940) called the same substance "angiotonin." More recently, an international agreement has combined the two names, creating "angiotensin."

Angiotensin is destroyed by a peptidase, called *angiotensinase*, present in the plasma. This enzyme is found in greater amount in several tissues, particularly the kidney, spleen, and liver. The red blood cells contain an appreciable amount of it The production and destruction of angiotensin seem to occur as follows.

Renin + angiotensinogen → angiotensin + x

Angiotensin + angiotensinase → inactive product

The amount of angiotensinogen contained in the plasma varies slightly in the different species but is around one unit for each 2 or 3 ml plasma One unit is the amount that forms an angiotensin unit, i e, one able to increase by 30 mm Hg the arterial pressure of a dog weighing 10 kg, anesthetized with chloralose It is clear that the total amount of angiotensinogen present in the blood can produce a considerable amount of angiotensin Moreover, angiotensinogen is continuously produced by the liver In effect, if all the angiotensinogen of the plasma were transformed after injection of a large dose of renin, it would be totally replaced in about 2 to 3 hr. The *renin of the various species presents certain differences* (Fasciolo et al, 1940) That of a pig is able to form angiotensin with the angiotensinogen of the pig, dog, rat, rabbit, etc Human angiotensinogen, however, forms angiotensin with renin of man, monkey, or ox, but not with that of other species This is important because

eign renin but also the animal's own renin (Wakerlin and Johnson, 1941)

Angiotensin The pressor action of angiotensin lasts only from 3 to 5 min, because it is rapidly destroyed in the blood and tissues. If angiotensin is *injected* by a continuous intravenous drip, *the* pressor effect persists during the whole time of the infusion. The prolonged action of renin is due to its slow destruction while angiotensin is produced

The study of the chemical *structure* of angiotensin has shown that it is a polypeptide; the number and *relationship* of the aminoacids it contains have been identified (Edman, 1945, Skeggs et al., 1955–1956, Peart et al., 1957). Angiotensin has been synthesized independently by two different groups (Bumpus et al., 1957; Rittel et al., 1957). According to Skeggs et al. (1954), the action of renin over angiotensinogen would create a decapeptide (angiotensin I). A conversion enzyme present in the plasma would remove two amino acids from angiotensin I, transforming it into an octapeptide (angiotensin II). According to Helmer (1954), only angiotensin II acts over the vascular musculature, but if angiotensin I is injected, it would be immediately converted in the blood to angiotensin II, having a vascular action.

The Renal Pressor System in the Hypertension Caused by Renal Ischemias. Houssay and *Fasciolo* (1937) grafted ischemic kidneys of *dogs with recent hypertension* in the neck of nephrectomized dogs, connecting the artery and vein of the kidney respectively to the carotid and jugular vein of the recipient animal. *This graft* was followed by a prolonged increase of arterial pressure in the recipient. Grafting of a normal kidney fails to elicit this action.

The substance responsible for this increase has characteristics similar to those of renin.

An increase in the plasma content of renin during the early stages of hypertension has been ascertained through the bioassay method developed by Leloir et al. (1940) and later *modified*. However, later stages do not reveal the same increase of renin even though the *pressure* remains elevated or even gradually increases It is evident that if renin is the agent responsible for the initial increase of pressure that follows renal ischemia, another agent or mechanism maintains the hypertension in later stages Theoretically, angiotensin could be *formed* within the ischemic kidney. If that were the case, renin would not be found in increased amount in the plasma *even though* the increase of angiotensin could be responsible for the hypertension.

The investigations of Skeggs et al (1951) seem to indicate that in the hypertension caused by renal ischemia, the blood of the dogs operated upon contains a greater amount of angiotensin, which would be responsible for the vasoconstriction and hypertension

The following facts *show* the role of the renal pressor mechanism in the hypertension following renal ischemia:

1. The blood concentration of angiotensin is increased. The studies of Skeggs et al. seem to show that the increase is moderate, though sufficient to maintain the elevated blood pressure. However, Scornick and Paludin (1961) could not confirm this, at least in benign hypertension.

2. Renal ischemia produces secretion of renin. Blood renin increases in the initial periods of hypertension but not in the subsequent stages.

3. The pressor action of renin and angiotensin has hemodynamic characteristics similar to that found in the hypertensive animal. There is diffuse vasoconstriction, and the increase of blood pressure is not inhibited by either sympatholytics or sympathectomy There are no modifications of the pulse rate or cardiac output.

4. A continuous intravenous infusion of renin causes a lasting hypertension in the rabbit This is not obtained with other pressor substances.

5. The heterologous injection of renin or the administration of antirenin serum neutralizes the pressor effect of renin and has a hypotensive effect in the hypertensive dog, both in the acute and in the chronic stages. The role of the renin-angiotensin system in the production of renal hypertension seems reasonably well established. This does not mean that other factors cannot contribute to the production or maintenance of hypertension Changes in reactivity of the arterioles to vasoconstrictor substances normally contained in the blood could play a certain role The experimental data are not always consistent, but it seems that vascular reactivity to epinephrine, norepinephrine, renin, and pitressin is somewhat increased in renal hypertension. However, the interpretation of these experimental results is difficult because of the different tension levels above which the increase is measured. Some authors have attributed the hypertension to other vasoconstrictor substances, such as tyramine, guanidine, 5-hydroxytryptamine, or other pressor substances However, evidence in favor of this hypothesis is insufficient

THE ROLE OF THE ENDOCRINE GLANDS The removal of the pituitary gland in the dog decreases the hypertension caused by renal ischemia (Page and Sweet, 1937) without, however, bringing the blood pressure to a normal level.

Compression of the renal arteries in animals deprived of the pituitary gland is followed by an increase of blood pressure.

The action of the pituitary gland is in the anterior lobe and is possibly mediated through the adrenal cortex. Extirpation of the cortical part of both adrenal glands is followed by a fall of blood pressure in the dog with hypertension caused by renal ischemia. The administration of adrenal steroids and adrenal extracts again increases the blood pressure but the previous level is not reached (Goldblatt, 1937). Similar results have been obtained in the hypertension of the rat caused by experimental perinephritis. The other endocrine glands seem not to play an important role in arterial hypertension caused by renal ischemia in the dog, as can be demonstrated by the effect of their removal in the hypertensive animal. However, in the partially nephrectomized rat, administration of various hormones causes an increase of blood pressure.

PRESSORECEPTORS AND HYPERTENSION. One of the interesting problems of hypertension caused by renal ischemia is the role of the pressoreceptors In the normal animal, every increase of blood pressure stimulates the aortic and carotid pressoreceptors, causing bradycardia and reflex vasodilatation. Goldblatt et al. (1940) showed that the extirpation of both carotid sinuses affects neither the development of hypertension by renal ischemia nor the level of pressure reached in the hypertensive animal. The tracings of action potentials of the carotid nerve show that in hypertensive animals, the threshold of discharge is placed at a higher level than in normal animals, showing that this has been an adaptation to the new level of pressure (McCubbin et al., 1956) However, in acute hypertension, this change of threshold seems not to occur. As the pressoreceptor reflexes start only at a higher level, not only do they not decrease blood pressure but contribute to its stabilization Some investigators believe that renal hypertension is initially produced by a humoral mechanism and that later on it is maintained by an extrarenal, probably neurogenic, mechanism

Hypertension and Pregnancy In the majority of animals with renal hypertension, pregnancy causes a decrease of blood pressure during the last period On the other hand, compression of the renal artery in the course of pregnancy exerts its usual pressor action

The decrease of pressure has been attributed to the influence of the fetal kidneys, to endocrine modifications, or to an effect of the placental circulation which is similar to that of an arteriovenous aneurysm.

Hypertension by Renal Compression. Page (1939) was able to produce persistent arterial hypertension in the dog, cat, or rabbit by wrapping the kidneys in cellophane or silk. The perirenal tissues react, forming a fibrous coat, which compresses the kidneys. This method is practical for use in small animals, in which compression of the renal arteries presents technical difficulties. Several materials, such as silk, cellophane, gauze soaked in collodium, etc., have been employed for wrapping the kidneys. Other methods include latex capsules or the compression caused by a ligature in the form of a figure eight that embraces both poles of each kidney and tends to rectify their curvature (Grollman, 1944).

In the case of unilateral perinephritis in the rat, the blood pressure rises after a latent period of 1 to 2 weeks (sometimes more). The rise is more rapid and marked and becomes permanent when both kidneys are compressed or when one kidney is removed while the other is compressed. The hypertension produced by unilateral perinephritis in the rat (in

such an irreversible change. The extirpation of the perinephritic kidney after a long period of hypertension usually is followed by a decrease of blood pressure—without complete normalization, however (Gaudino, 1944). In some of the animals, there is no drop of blood pressure; this has also been observed in the unilateral ischemia of the rabbit (Wilson and Byrom, 1941). The hypertension persisting after removal of the organ responsible for its onset may be related to the secondary arterial lesions that are found in the kidneys. The severity of the lesions found in the undamaged kidney seems to be proportional to the severity and duration of the hypertension. A truly vicious circle then occurs, so that the renal lesions cause hypertension and this contributes to the production of vascular lesions in the undamaged kidney which are capable of maintaining and increasing the hypertension. The mechanism of producing hypertension by perinephritis seems to be similar to that caused by ischemia, i.e., an ischemic effect related to the increase of intrarenal pressure without any compression of the hilus. Some authors believe that the increase of arterial pressure is caused initially by the renin-angiotensin mechanism. Later, however, it would be maintained by an extrarenal mechanism, and the removal of the kidney would not be followed by improvement.

Hypertension Caused by Reduction of Renal Tissue. Chanutin and Ferris (1932) proved that in the rat, removal of about 80 per cent of renal tissue is followed by an increase of blood pressure. Usually, from one-half to three-quarters of one kidney is resected and, in a second operation, the other kidney is removed. One to two weeks after the second operation, the blood pressure starts increasing and reaches its maximum between 2 and 4 months later. The rats show renal insufficiency, polyuria, and proteinuria. In the fragment of kidney which is left, glomerular, tubular, and vascular alterations are observed. The mechanism of this hypertension is still unknown. Some investigators believe that it could be due to renal ischemia secondary to the circulatory disturbance produced by the cicatricial retraction of the organ that has been operated upon. Even though no significant diminution of blood volume per gram of kidney is apparent, the functional overload of the fragment of kidney is such that a relative ischemia has been postulated. It is possible that this hypertension is connected to some deficiency of renal function and has a similar mechanism to that found in totally nephrectomized animals. The fact that in the rat, a reduction of renal tissue sensitizes the animal to the pressor action of several substances which are ineffective in an intact rat seems to confirm this viewpoint. These substances are Doca, sodium chloride 1 per cent, thyroid powder, tyrotropin, somatotropin, serum or placental gonadotropin (the latter in males only).

Hypertension Following Nephrectomy. Braun-Menéndez and von Euler (1947) observed an increase of blood pressure in nephrectomized rats, and Grollman et al. (1949) confirmed this observation in dogs with bilateral nephrectomy maintained alive for weeks or months through use of an artificial kidney or by means of peritoneal lavage. Without the above procedures, nephrectomy is followed by death in the dog after 3 to 7 days, a period

which is too short for producing hypertension. In the nephrectomized animal the blood pressure starts to rise between the tenth and the fourteenth days after nephrectomy. However, even before the appearance of hypertension, hemodynamic disorders occur. Forty-eight hours after nephrectomy the blood pressure is normal, but cardiac output is increased and the peripheral resistances have decreased (Krieger and Hamilton, 1958).

It is possible to cause hypertension from 24 to 48 hr after a bilateral nephrectomy by intraperitoneal administration of saline or other salt solutions (Orbison et al., 1952). In the dog, there is a direct relationship between the degree of hydration, the volume of interstitial fluid, and the hypertension. In the majority of animals the increase of blood pressure is associated with an increase in weight However, some animals develop hypertension without fluid or sodium retention. This would indicate that this is not the only factor in the production of hypertension. The increase of sodium increases the vascular lesions, the hypertension and the hyponatremia have a protective effect

Hypertension is also increased by diets rich in proteins Handler (1958) found that the administration of ACTH increases blood pressure in bilaterally nephrectomized rats Vomiting and diarrhea dehydrate these animals and prevent the increase of pressure. This hypertension seems to be due to an increase of the peripheral resistances, because no changes in cardiac output and blood volume have been found

A total sympathectomy (Houck, 1956) does not prevent the appearance of hypertension after nephrectomy, excluding the possibility of a neurogenic vasoconstriction The reactivity of the vessels to norepinephrine and other pressor substances is increased, but there is no convincing proof of the existence of pressor substances in the blood of nephrectomized hypertensive dogs. As it may be, the hypertension does not seem due to retention of pressor substances normally eliminated in the urine Moreover, bilateral ureteral ligation causes a discrete elevation of blood pressure, which reaches its maximum at about 4 days from the ligature. This hypertension seems to be connected with the circulatory disturbances caused by the hydronephrosis, and its mechanism is similar to that of the hypertension which follows renal ischemia. The blood pressure tends to drop in the following days if the life of the animal is prolonged by peritoneal lavage (Grollman et al., 1951). The unilateral ligature of the ureter also causes a transitory increase of blood pressure. If a ureter is connected to the vena cava and the other kidney is removed, retention of metabolites, as in bilateral nephrectomy, occurs. However, hypertension does not arise when the life is prolonged by peritoneal dialysis. Removal of normal renal tissue seems necessary for its production; for this reason it is thought that the renal tissue produces some hypotensive substance, the lack of which causes hypertension. The protective action of the nonischemic kidney in the form of hypertension caused by renal ischemia suggests a similar mechanism Also the transplantation of normal kidneys decreases the blood pressure in the nephrectomized dog, while other tissues do not exert this effect (Kolff and Page, 1954). It has been theorized that the normal kidney can destroy some pressor substance which forms in the organism.

In this form of hypertension, the changes of water and salt metabolism are severe and represent a factor in the production and aggravation of hypertension which will be discussed later. Increase of sodium and decrease of potassium have been found in the aortic walls of these animals It is possible that modifications of the sodium and potassium of the arteriolar musculature increase their tone and play a role in the production of this type of hypertension In chronic hypertension caused by unilateral renal ischemia of the rabbit (Daniel et al., 1954) or by unilateral perinephritis in the dog (Kolff and Page, 1955), removal of the kidney does not cause a drop of blood pressure, so that hypertension persists till death These facts can be interpreted by supposing that the chronic hypertension caused by a renal mechanism is later maintained by an extrarenal factor, or that when the kidney is removed, renal hypertension is immediately followed by the type of renoprival hypertension

The form of hypertension caused by nephrectomy has vascular alterations similar to those found in human or experimental malignant hypertension The more acute lesions represented by necrosis and hemorrhages in the heart and necrosis in the media of the small arteries and arterioles make their appearance

in the first days after nephrectomy. If the life of the animal is prolonged, hyalinization of the media is found in the arteries and arterioles The vascular lumen is usually narrowed and lateralized. Hyperplasia of the muscular tissue, subendothelial deposits of a hyaline material, and proliferation of the intima can also be found The chronic vascular lesions do not occur in the animals with ureteral ligation when life is prolonged by dialysis This led some investigators to postulate that the presence of renal tissue is able to prevent such lesions.

Other Types of Renal Hypertension. Other procedures that have been employed for the production of renal hypertension are listed on page 12-61(Supp.). Some of them are only of historical interest and will not be considered. Others, however, are interesting because they reveal mechanisms by which renal function can be altered and hypertension caused.

Kubicek et al. (1953) were able to produce hypertension in the dog by means of prolonged electrical stimulation of either the splanchnics or of the renal nerves When the stimulation is terminated, the blood pressure returns to normal These results seem to indicate that vasoconstriction can produce a renal ischemia that is sufficiently severe and prolonged for activating the renal pressor mechanism. That this activation is directly originated through a neurogenic mechanism, not through ischemia, cannot be disregarded

The changes in renal function that cause arterial hypertension may be caused by metabolic alterations. In rats, a short period of deprivation of choline or potassium during lactation is followed by hemorrhagic renal lesions and then by hypertension (Handler et al, 1951).

Masugi's experiments (1934) showed the importance of the mechanism of immunity. The renal alterations that elicit hypertension are caused by a nephrotoxic serum obtained by inoculating one animal species with the renal extract of another.

Mechanism of Renal Arterial Hypertension. With the exception of renal ischemia, the mechanism by which hypertension occurs in the various alterations of the renal function has not been sufficiently studied. It appears that in hypertension caused by renal ischemia, the increase of blood pressure is due to one or more substances poured by the kidney into the circulation. Unilateral ischemia in the dog causes a temporary hypertension, and the removal of the ischemic kidney rapidly normalizes the blood pressure. Similar results have been obtained in clinical cases with hypertension secondary to unilateral renal lesion. It is apparent that in these cases, the increase in blood pressure cannot be due to lack of production by the kidney of any hypothetic substance, neither can it be attributed to the pressor effects of renal insufficiency nor to the lack of an endocrine function of this organ. In the opinion of the author, the proofs that the hypertension caused by renal ischemia is due to renin-angiotensin mechanism seem reasonably good without being conclusive. Final proof will require greater information about the angiotensin content of the blood, in both the clinical and the experimental forms of hypertension On the other hand, the hypertension caused by nephrectomy cannot be explained by a similar mechanism. Here the hypertension is due to the lack of renal tissue, to the absence of some function of the kidney; the latter may consist in the destruction of pressor substance, the lack of a hypothetic depressor substance, or the alterations of the blood composition produced by the abolition of the excretory function. The last mechanism seems excluded by experiments in which abolition of the excretory function of the kidney without its removal is not followed by hypertension. Moreover, the healthy renal tissue protects against the pressor effect of the ischemic kidney, and bilateral nephrectomy sensitizes the vessels to the pressor action of certain substances, mainly renin The cause of the protection or potentiation is not known, it could be due to modification in the sodium and potassium content of the arteriolar muscles

The above may be summarized as follows, the hypertension caused by renal ischemia and that caused by nephrectomy cannot be explained by the same mechanism—there are at least two mechanisms by which the kidney is able to cause hypertension. It is possible that both mechanisms operate in certain cases of hypertension of renal etiology and that the increase of blood pressure depends upon the relationship between the amount of ischemic and normal renal tissues.

The Role of the Adrenal Glands in Arterial Hypertension. The role of the adrenal glands in arterial hypertension is not completely clear, even though there is no doubt that these

which is too short for producing hypertension. In the nephrectomized animal the blood pressure starts to rise between the tenth and the fourteenth days after nephrectomy. However, even before the appearance of hypertension, hemodynamic disorders occur. Forty-eight hours after nephrectomy the blood pressure is normal, but cardiac output is increased and the peripheral resistances have decreased (Krieger and Hamilton, 1958).

It is possible to cause hypertension from 24 to 48 hr after a bilateral nephrectomy by intraperitoneal administration of saline or other salt solutions (Orbison et al., 1952). In the dog, there is a direct relationship between the degree of hydration, the volume of interstitial fluid, and the hypertension In the majority of animals the increase of blood pressure is associated with an increase in weight However, some animals develop hypertension without fluid or sodium retention This would indicate that this is not the only factor in the production of hypertension. The increase of sodium increases the vascular lesions; the hypertension and the hyponatremia have a protective effect

Hypertension is also increased by diets rich in proteins. Handler (1958) found that the administration of ACTH increases blood pressure in bilaterally nephrectomized rats Vomiting and diarrhea dehydrate these animals and prevent the increase of pressure. This hypertension seems to be due to an increase of the peripheral resistances, because no changes in cardiac output and blood volume have been found.

A total sympathectomy (Houck, 1956) does not prevent the appearance of hypertension after nephrectomy, excluding the possibility of a neurogenic vasoconstriction The reactivity of the vessels to norepinephrine and other pressor substances is increased; but there is no convincing proof of the existence of pressor substances in the blood of nephrectomized hypertensive dogs. As it may be, the hypertension does not seem due to retention of pressor substances normally eliminated in the urine Moreover, bilateral ureteral ligation causes a discrete elevation of blood pressure, which reaches its maximum at about 4 days from the ligature. This hypertension seems to be connected with the circulatory disturbances caused by the hydronephrosis, and its mechanism is similar to that of the hypertension which follows renal ischemia. The blood pressure tends to drop in the following days if the life of the animal is prolonged by peritoneal lavage (Grollman et al., 1951). The unilateral ligature of the ureter also causes a transitory increase of blood pressure. If a ureter is connected to the vena cava and the other kidney is removed, retention of metabolites, as in bilateral nephrectomy, occurs. However, hypertension does not arise when the life is prolonged by peritoneal dialysis. Removal of normal renal tissue seems necessary for its production; for this reason it is thought that the renal tissue produces some hypotensive substance, the lack of which causes hypertension The protective action of the nonischemic kidney in the form of hypertension caused by renal ischemia suggests a similar mechanism Also the transplantation of normal kidneys decreases the blood pressure in the nephrectomized dog, while other tissues do not exert this effect (Kolff and Page, 1954). It has been theorized that the normal kidney can destroy some pressor substance which forms in the organism.

In this form of hypertension, the changes of water and salt metabolism are severe and represent a factor in the production and aggravation of hypertension which will be discussed later Increase of sodium and decrease of potassium have been found in the aortic walls of these animals It is possible that modifications of the sodium and potassium of the arteriolar musculature increase their tone and play a role in the production of this type of hypertension. In chronic hypertension caused by unilateral renal ischemia of the rabbit (Daniel et al, 1954) or by unilateral perinephritis in the dog (Kolff and Page, 1955), removal of the kidney does not cause a drop of blood pressure, so that hypertension persists till death These facts can be interpreted by supposing that the chronic hypertension caused by a renal mechanism is later maintained by an extrarenal factor, or that when the kidney is removed, renal hypertension is immediately followed by the type of renoprival hypertension

The form of hypertension caused by nephrectomy has vascular alterations similar to those found in human or experimental malignant hypertension The more acute lesions represented by necrosis and hemorrhages in the heart and necrosis in the media of the small arteries and arterioles make their appearance

1952). It is necessary to recognize that these arguments are indirect and not conclusive. On the other hand, some facts are against the participation of the kidney in this type of hypertension. Blood pressure continues to rise in rats rendered hypertensive by Doca even after bilateral nephrectomy (Hall and Hall, 1949); a kidney from such rats grafted onto a normal recipient fails to exert any pressor effect, while that of an animal with renal hypertension is capable of elevating the blood pressure (Prado and Valle, 1952). The mechanism of hypertension that persists after the administration of Doca has been studied by Green et al. (1952). The elevation does not seem to be mediated by the adrenals, thyroid, parathyroid, or gonads, however, the hypertension is reduced by removal of the pituitary and kidney

The sensitivity of animals with corticoid or metacorticoid hypertension to various pressor substances, especially renin, seems to be slightly increased. However, the interpretation of these investigations is difficult. It has been shown in the rabbit that Doca increases in vitro the sensitivity of the aortic musculature to epinephrine. There is a close relationship between Doca and the metabolism of water and sodium. Changes of the latter could be responsible for the hypertension. Doca increases the specific appetite of the rat for salt (Braun-Menéndez and Brandt, 1952) and is followed by salt retention, increase of the interstitial fluid, increase of intracellular sodium, and decrease of intracellular potassium

Pressor Action of Cortisone. Cortisone, hydrocortisone, and their derivatives may cause hypertension, either clinically or experimentally, under favorable circumstances The effect of cortisone is different from that of Doca in that it does not require the presence of sodium or potassium in order to exert its pressor effect. In the rat which is rendered hypertensive through reduction of renal tissue, the lack of potassium causes a drop in blood pressure, which can be abolished by the administration of cortisone or ACTH. Cortisone causes hypertension in adrenalectomized rats placed on a salt-poor diet; Doca has no pressor action in such animals If salt is added, then Doca causes an increase of blood pressure while the pressor effect of cortisone seems to be weaker. Actually, the pressor effect of cortisone seems to be potentiated by alterations of kidney function, loss of potassium, and adrenalectomy, but not by the lack of sodium Some fluorine derivatives, such as 9-α-fluorocortisone and 1-dehydro-9α-fluorocortisone, are several times more potent in respect to pressor action than cortisone or hydrocortisone. Paradoxically, in the majority of the cases, cortisone is able to abolish the hypertension that develops in parabiotic rats.

Corticosterone in doses of 5 mg per rat, per day, causes hypertension, polydypsia, and vascular lesions (Skelton, 1958).

Aldosterone. Primary hyperaldosteronism is accompanied by hypertension; in hypertension, aldosterone excretion seems to be increased. In the rat, a dose of from 0.25 to 1 μg of aldosterone per day causes arterial hypertension and vascular lesions (Kumar et al., 1957). However, other investigators proved that aldosterone administration in the rat has little or no pressor effect (Fregly and Arean, 1959), thus establishing a clear difference between the actions of Doca and aldosterone. No doubt further studies are needed in this field.

Hypertension Caused by Regeneration of the Adrenal Glands. The regeneration of the adrenal cortex in young female rats which have undergone unilateral nephrectomy and which drink a 1 per cent sodium chloride solution causes hypertension and vascular lesions similar to those produced by several corticosteroids or their derivatives (Skelton, 1956). The administration of saline solution is essential for the onset of hypertension, but when hypertension has been established, saline solution can be omitted without causing a decrease in blood pressure. Ligation of the adrenal pedicle causes a similar picture Adrenal-enucleated rats present periarteritis nodosa, panarteritis, fibrinoid degeneration, and arteriolar wall necrosis, these lesions are similar to those found in malignant renal hypertension and in corticoid or metacorticoid hypertension.

MECHANISM OF ARTERIAL HYPERTENSION BY ADRENAL REGENERATION. The hypertension is clearly associated with the regeneration of the adrenal glands. If after enucleation or transplantation of the gland, its regeneration is inhibited by removal of the pituitary, the hypertension fails to appear. Substances such as anferone B which block the synthesis of corticoids by the adrenal glands also have an inhibiting effect. Somatotropin and thyroxin,

Fig. 12-10. Nephrosclerosis produced by DOCA. Two glomeruli showing different degrees of sclerosis. One arteriole shows fibrinoid degeneration of the media; the other shows replacement of the media by connective tissue. Gomori's aldehyde fuchsin. ×160. (*From Skelton A M A. Arch. Path.* 1955)

glands do play such a role. It is known that it is possible to produce hypertension through the administration of desoxycorticosterone, cortisone, corticosterone or one of its derivatives, and also through the enucleation of the adrenal glands. In renal hypertension, changes of the adrenal glands have been observed and their surgical removal decreases or normalizes blood pressure.

PRESSURE ACTION OF DESOXYCORTICOSTERONE. Desoxycorticosterone is able to produce increased arterial pressure in several species but the rat is the animal in which its effect has been best studied (Selye et al., 1943) (Fig. 12-10). The drug is administered in the form of oil or microcrystals, in a daily dose of 1 to 2 mg. It is conveniently given through subcutaneous implantation of pellets containing around 20 mg Doca. Desoxycorticosterone produces an increase of arterial pressure in normal rats, suprarenoprives, or rats with renal hypertension. The arterial pressure starts to ascend after the first week, to reach its maximum in 6 to 8 weeks.

The pressor effect of Doca is potentiated by the salt content of the diet. Moreover, in the absence of sodium, Doca fails to exert any pressor action and does not produce the typical vascular alterations. Potassium seems also to be indispensable for the development of the pressor action (Rosenman et al., 1954). A decrease of renal tissue increases the effects and makes it possible to obtain a more rapid and constant hypertension It is customary to sensitize the rats through a unilateral nephrectomy, and to replace water in the diet by a 1 per cent solution of sodium chloride. The pressor effect of Doca persists in a large percentage of animals after withdrawal of the drug; this has been called *metacorticoid hypertension*.

ANATOMIC ALTERATIONS PRODUCED BY DOCA. The administration of Doca causes vascular lesions in the heart and kidneys, but also in other organs. The kidneys become hypertrophied; microscopically they show glomerular and tubular lesions. The glomeruli show deposits of hyaline material (fibrinoid) and fibroplastic periglomerular proliferation. These alterations may evolve to a complete glomerular fibrosis. The arteries and arterioles show hyaline degeneration of the media and necrosis of the vascular walls. The media may be replaced by connective tissue, while the intima shows deposits of a subendothelial hyaline material with total or partial occlusion of the lumen of the artery. The renal tubules are distended and full of hyaline material. The vascular lesions of other tissues are similar to those of the kidneys but less severe. Methyl-androstenediol, an androgenic steroid, can cause hypertension with lesions similar to those described above (Skelton, 1955). Selye (1944) observed that this sclerotizing action of Doca and of other related substances is neutralized by other steroids, derived from the androstane, which produce tubular hypertrophy and hyperplasia without sclerosis

MECHANISM OF THE HYPERTENSION CAUSED BY DOCA. The mechanism of hypertension caused by Doca is obscure. The predominance of renal vascular lesions leads one to suspect the participation of the kidney. Several facts seem to confirm this viewpoint: (1) the hypertension is potentiated by partial nephrectomy, (2) total nephrectomy decreases the metacorticoid hypertension (Green et al, 1952), even though it seems ineffective *during* Doca administration, (3) the pressor effect of renin is less marked in adrenalectomized animals and is greater in animals treated with Doca and salt; Doca decreases the renin content of the kidneys, (4) administration of renin increases the vascular alterations produced by Doca, injected in rats rendered hypertensive by means of Doca and salt, it causes a picture similar to that of eclampsia, with convulsions, edema, oliguria, azotemia, anasarca, and tubular necrosis (Masson et al,

an important role in hypertension. Its removal does not affect the blood pressure of animals with renal hypertension, but injection of pitressin is followed by a drop of blood pressure in the rat with renal hypertension or hypertension caused by administration of Doca (Friedman et al, 1955). This action of pitressin seems to be related to modifications in the excretion of electrolytes The urine of hypertensive subjects (man, dog, rat) has demonstrated a greater antidiuretic activity than the normal urine It is possible that this fact is related to the alterations of water and salt metabolism that are commonly found in hypertension

In conclusion, a deficiency of pituitary function tends to decrease the hypertension, while an excess has an opposite effect. The mechanism of this action is not completely clear, but most data seem to indicate that it is closely linked to the adrenal function. An adrenal deficiency resulting from hypophysectomy is probably responsible for the fall of blood pressure in the hypertensive subject The hypertensive action of the anterior lobe of the pituitary gland and of somatotropin is likely to be obtained through a stimulation of the adrenal glands

The Thyroid. Thyroidectomy has no effect on blood pressure in the dog with hypertension caused by renal ischemia However, in the rat with renal hypertension, thyroidectomy or the administration of propylthiouracil reduces the level of blood pressure or prevents hypertension These measures also reduce the blood pressure of the rat treated with Doca and salt, and prevent the increase of blood pressure and the vascular lesions occurring in this condition Thyroidectomy also protects against nephrosclerosis and myocarditis in the form of hypertension caused by methyl-androstenadiol and chlorocortisol Thyroid administration elicits an increase of blood pressure in the partially nephrectomized rat. Thyrotropin has a similar action in animals with intact thyroid but not in thyroidectomized animals (Braun-Menéndez and Penhos, 1953)

The mechanism of the thyroid pressor effect is unknown. It has been shown that the reactivity of the vessels to pressor substances is increased in animals treated with thyroid extract, and is decreased after thyroidectomy.

Other Glands. The parathyroids, the gonads, and the pancreas do not seem to be connected with the mechanism of production of hypertension The removal of the medulla of both adrenal glands does not modify the blood pressure of animals with renal hypertension. The gonadotropins of the serum or corion have a pressor action in the male partially nephrectomized rat.

Sodium and Potassium in Arterial Hypertension. The modifications of the water and salt sodium balance in hypertension have been intensively studied, and their importance has been recognized in the last 10 years However, some of the typical changes that follow hypertension seem to be related more to the simultaneous renal changes than to the pressor mechanism

MODIFICATIONS OF THE HYDROSALINE METABOLISM IN HYPERTENSIVES. The rat with renal hypertension produced either by reduction of the renal mass or by compression of the kidney (ligature-in-eight or perinephritis) shows marked alterations of water and salt metabolism. Polyuria, polydipsia, and reduction in the concentration power of the kidney are produced The interstitial fluid increases, mostly in the initial stages of hypertension, but blood pressure may rise without such an increase. If the hypertensive rat can choose between drinking water and a sodium chloride solution, it prefers the latter whenever the molarity of the solution is less than 0 06 *M* (Fregly, 1959); if the molarity is above 0.075 *M*, it prefers water. Normal rats with a similar alternative choose the salt solution until a concentration of 0.105 *M* is reached, i e , they accept solutions having a greater molarity. The rat rendered hypertensive through Doca or cortisone administration or by adrenalectomy shows alteration of water and salt sodium balance similar to that described above.

The velocity with which the kidney eliminates an overload of sodium is increased in human hypertension, as well as in experimental renal or adrenal hypertension The above alterations of water and salt metabolism are not limited to the hypertensive animal but are also found (though to a less marked degree) in animals which have been submitted to the same experimental procedure but which have not developed hypertension It seems reasonable to assume that they are due to some degree of renal insufficiency. This seems confirmed by the fact that in the dog, where renal ischemia is followed by hypertension

however, potentiate this hypertension; ACTH fails to exert any significant action. Removal of the thyroid gland prevents the occurrence of hypertension. It has been thought that hypertension and the vascular lesions are the result of an increase in secretion of the regenerated gland or of a hormonal imbalance However, no increase of aldosterone or corticosterone was found in the blood of the renal vein on the side of the regenerated gland (Brogi and Pellegrino, 1958; Masson et al, 1958). Actually, the aldosterone content seems to be diminished.

The magnitude of the renal lesions has concentrated attention on the kidneys as the organ responsible for the hypertension, but, so far, there are no conclusive data

The Adrenal Glands in Renal Hypertension. In hypertension caused by renal ischemia in the dog, all the investigators have found that the removal of the adrenal glands causes a fall in blood pressure to normal or subnormal levels Renal ischemia in the adrenalectomized animal is not followed by hypertension. The administration of cortical extract restores the hypertension, but the level of blood pressure existing prior to adrenal removal is not reached.

In the rat rendered hypertensive by perinephritis, adrenalectomy is followed by a drop of blood pressure to normal or subnormal levels, and the arterial pressure can be increased again by administration of Doca. On the other hand, it has been found that it is possible to obtain hypertension in the adrenalectomized rat through wrapping the kidneys in a latex capsule. In the hypertension caused by nephrectomy, subsequent adrenalectomy fails to produce a fall of blood pressure, even though there are some discordant results In regard to the adrenal changes in renal hypertension, hypertrophy of these glands has been found in rats made hypertensive by perinephritis

Substances That Block Corticoid Action. Sturtevant et al. (1959) studied the effect of one steroid (SC 5233) in adrenalectomized rats receiving Doca and found that it is able to reverse the trend toward sodium retention and loss of potassium. It also blocks the urinary effects of aldosterone, hydrocortisone, and other steroids It has no androgenic, anabolic, or estrogenic effects SC 5233 inhibits the development of hypertension by Doca and reduces the metacorticoid hypertension in the rat. Another steroid (SC 6584) has similar characteristics in the metacorticoid and perinephritic hypertension of the rat, thus revealing the role of the adrenal glands in renal hypertension.

Role of the Pituitary Gland. Because of contradictory experimental results, the role of the pituitary in renal hypertension is not clear. *Total extracts* or *somatotropin* increase blood pressure in the rat (Selye, 1951). Somatotropin is the most effective, mostly in rats with unilateral nephrectomy, though it seems to be ineffective in thyroidectomized rats Somatotropin causes an increase of weight of the abdominal organs, produces nephrosclerotic lesions, and aggravates the renal lesions produced in rats by choline deficiency as well as the vascular lesions produced by methylandrostenediol (Selye and Salgado, 1957). Selye and Bois (1956) found that the nephrotoxic effect of somatotropin in the rat is potentiated by ACTH, and that the adrenal glands are necessary in order for it to occur. It is possible that somatotropin acts by liberating or increasing the production of some steroid or that it needs the presence of some hormone normally produced by the adrenal glands in order to exert its action. *ACTH* seems to have shown also its pressor action in special conditions (Handler and Bernheim, 1950), and is able to produce important vascular lesions in the adult rat with unilateral nephrectomy (Wexler and Miller, 1958).

Removal of the pituitary gland causes a drop of blood pressure in the dog, as well as in the rat, with renal hypertension. In the dog, the blood pressure can reach either normal levels or a slightly higher level In the hypertensive rat, hypertension can be restored by ACTH administration In dogs in which the pituitary gland has been removed, renal ischemia causes an increase of blood pressure, and, if there is a subsequent drop, increase of the ischemia is followed by a new increase of blood pressure

Hypophysectomy also reduces the endocrine form of hypertension. Removal of the pituitary gland is followed by a drop of blood pressure and a decrease of the vascular lesions in rats that have been treated with Doca (Hall and Hall, 1959)

POSTERIOR LOBE OF THE PITUITARY GLAND. The posterior lobe does not seem to have

an important role in hypertension Its removal does not affect the blood pressure of animals with renal hypertension, but injection of pitressin is followed by a drop of blood [illegible]

sin seems to be related to modifications in the excretion of electrolytes. The urine of hypertensive subjects (man, dog, rat) has demonstrated a greater antidiuretic activity than the normal urine It is possible that this fact is related to the alterations of water and salt metabolism that are commonly found in hypertension

In conclusion, a deficiency of pituitary function tends to decrease the hypertension, while an excess has an opposite effect The mechanism of this action is not completely clear, but most data seem to indicate that it is closely linked to the adrenal function. An adrenal deficiency resulting from hypophysectomy is probably responsible for the fall of blood pressure in the hypertensive subject. The hypertensive action of the anterior lobe of the pituitary gland and of somatotropin is likely to be obtained through a stimulation of the adrenal glands

The Thyroid. Thyroidectomy has no effect on blood pressure in the dog with hypertension caused by renal ischemia. However, in the rat with renal hypertension, thyroidectomy or the administration of propylthiouracil reduces the level of blood pressure or prevents hypertension These measures also reduce the blood pressure of the rat treated with Doca and salt, and prevent the increase of blood pressure and the vascular lesions occurring in this condition Thyroidectomy also protects against nephrosclerosis and myocarditis in the form of hypertension caused by methyl-androstenadiol and chlorocortisol Thyroid administration elicits an increase of blood pressure in the partially nephrectomized rat. Thyrotropin has a similar action in animals with intact thyroid but not in thyroidectomized animals (Braun-Menéndez and Penhos, 1953)

The mechanism of the thyroid pressor effect is unknown. It has been shown that the reactivity of the vessels to pressor substances is increased in animals treated with thyroid extract, and is decreased after thyroidectomy.

Other Glands. The parathyroids, the gonads, and the pancreas do not seem to be connected with the mechanism of production of hypertension The removal of the medulla of both adrenal glands does not modify the blood pressure of animals with renal hypertension. The gonadotropins of the serum or corion have a pressor action in the male partially nephrectomized rat.

Sodium and Potassium in Arterial Hypertension. The modifications of the water and salt sodium balance in hypertension have been intensively studied, and their importance has been recognized in the last 10 years. However, some of the typical changes that follow hypertension seem to be related more to the simultaneous renal changes than to the pressor mechanism.

MODIFICATIONS OF THE HYDROSALINE METABOLISM IN HYPERTENSIVES The rat with renal hypertension produced either by reduction of the renal mass or by compression of the kidney (ligature-in-eight or perinephritis) shows marked alterations of water and salt metabolism. Polyuria, polydipsia, and reduction in the concentration power of the kidney are produced. The interstitial fluid increases, mostly in the initial stages of hypertension, but blood pressure may rise without such an increase. If the hypertensive rat can choose between drinking water and a sodium chloride solution, it prefers the latter whenever the molarity of the solution is less than 0.06 *M* (Fregly, 1959); if the molarity is above 0 075 *M*, it prefers water. Normal rats with a similar alternative choose the salt solution until a concentration of 0.105 *M* is reached, i e., they accept solutions having a greater molarity. The rat rendered hypertensive through Doca or cortisone administration or by adrenalectomy shows alteration of water and salt sodium balance similar to that described above

The velocity with which the kidney eliminates an overload of sodium is increased in human hypertension, as well as in experimental renal or adrenal hypertension. The above alterations of water and salt metabolism are not limited to the hypertensive animal but are also found (though to a less marked degree) in animals which have been submitted to the same experimental procedure but which have not developed hypertension It seems reasonable to assume that they are due to some degree of renal insufficiency. This seems confirmed by the fact that in the dog, where renal ischemia is followed by hypertension

without alteration of the excretory function of the kidneys, the alterations of water and salt metabolism are not clearly present.

THE SODIUM AND POTASSIUM OF THE TISSUES The electrolyte composition of the tissues has been intensively studied, but the results are difficult to interpret. On the one hand, the intracellular fluid composition varies in various tissues of the body and it would be incorrect to extend to all tissues the data obtained in one. On the other hand, the composition of the intracellular fluid is deduced on the basis of data obtained from analysis of a fragment of tissue, so that it is necessary to advance certain hypotheses which are not totally justified. The results of Tobian and Binion (1954) showed that the content of sodium and potassium is increased in the aorta of rats which have renal hypertension or which have received Doca. The hypertensive action of certain drugs, such as reserpine, is associated with the decrease of these cations in the aorta, and potassium restriction has a similar effect. In rats made hypertensive by renal compression, restriction of potassium in the diet is followed by a drop of blood pressure and a decrease of potassium in the aorta, an effect that can be reversed by the administration of cortisone. Potassium restriction also reduces the blood pressure of normal rats, again together with a decrease of potassium in the aorta. The blood pressure can be normalized by the administration of cortisone.

THE SODIUM AND POTASSIUM OF THE DIET The pressor effects of an overload of sodium have been studied in several conditions, and the results are generally similar. In the rat, the administration of a diet rich in sodium causes hypertension which is associated with renal insufficiency and vascular alterations (Meneely et al, 1953). In birds, Selye has described a sclerotizing effect on the kidney resulting from the administration of an excess of salt. In the nephrectomized dog, ingestion of saline solutions accelerates the appearance of hypertension, and partially nephrectomized rats become hypertensive if they drink a 1 per cent salt solution One per cent or 2 per cent potassium solutions have no pressor effect in partially nephrectomized rats Sodium restriction somewhat reduces renal hypertension and counteracts the hypertensive action of Doca but not that of cortisone. Restriction of potassium causes a reduction of the effect of Doca but not of cortisone. Potassium deficiency, prolonged for some weeks, causes in the rat renal alterations (glomerular atrophy and tubular dilatation) which are able to cause hypertension.

MECHANISM OF THE VASCULAR ACTIONS OF SODIUM AND POTASSIUM. The above-mentioned facts show that modifications in water and sodium balance somehow are involved in the mechanism of hypertension. It is not clear, as yet, how these alterations succeed in causing vascular effects, but some of the possibilities should be discussed.

Change in Vascular Sensitivity. The resting potential of several excitable tissues (nerve, smooth, and skeletal muscles) depends upon the relationship between the electrolyte concentrations (especially potassium) within and outside the cell. Bohr et al. (1958), working with fragments of rabbit aorta in Krebs solution, observed that the response to epinephrine increases when the sodium concentration in the fluid decreases, and vice versa On the contrary, if the potassium concentration was increased, the sensitivity of the preparation increased, and if it was reduced, it decreased. Similar results have been obtained in sections of colon (Friedman, 1959). The pressor effect of several drugs seems to be associated with a shift of sodium from the intracellular to the extracellular fluid. Although the electrolyte changes in the arteriolar muscle in hypertension are not known, these studies favor the concept that modifications in the reactivity of the vessels to vasoconstrictor substances play a certain role in the pressor effects of sodium and potassium

Renal Alterations. The vascular and renal alterations produced by an overload of sodium or a potassium deficiency seem to point out that the hypertension obtained in such way may be produced by a renal mechanism. At present, however, there is not enough evidence to confirm or deny such a possibility.

Alterations of the Adrenal Function. The aldosterone secretion is controlled by the extracellular concentration of sodium and potassium and also by the volume of the liquid compartments Increase of potassium, diminution of sodium, and reduction of the extracellular volume increase the production of aldosterone It is possible to postulate that if the secretion of aldosterone is excessive, an endocrine imbalance would occur, causing renal

and vascular alterations, followed by hypertension

Arteriolar Edema The increase of water in the arteriolar wall could reduce the vascular lumen and increases the total peripheral resistance, thus favoring hypertension.

NEUROGENIC ARTERIAL HYPERTENSION

Increase of Intracranial Pressure. It is well known that a sudden increase in the pressure of the spinal fluid causes arterial hypertension. Dixon and Heller (1932) showed that it is possible to obtain persistent hypertension in the dog through cisternal injection of a suspension of kaolin. This substance causes an obstruction of the subarachnoid spaces, limiting the reabsorption of fluid and causing an increase in intracranial pressure. Not all investigators are in agreement about the possibility of obtaining permanent or persistent hypertension with this procedure. Some have shown that the increase of blood pressure is moderate or transitory. The arterial hypertension caused by intracranial hypertension seems to be due to *anoxia of the vasomotor centers*, secondary to the ischemia that results from the compression of the central nervous system The sympathetic stimuli discharged by the vasoconstrictor center cause a reduction of the arteriolar lumen and probably a discharge of epinephrine or norepinephrine by the adrenal medulla According to some investigators, renal denervation prevents or cures this form of hypertension, this would suggest that the renal pressor system can be activated by sympathetic hypertonus.

Section of Carotid and Aortic Nerves. Koch and Mies (1929) obtained a persistent hypertension in the rabbit through section of the aortic and carotid nerves Other investigators confirmed these results in the dog (See Fig 12-11) The blood pressure remains elevated for years, but in some animals shows a tendency to drop and may become normal, a fact which has been attributed to regeneration of the vasodepressor trunks The increase in pressure obtained with this method is considerable, the systolic pressure may even reach 300 mm Hg The blood pressure increases abruptly after section of the last depressor nerve, but this increase is of short duration Usually, persistent hypertension starts 48 hr after cutting of the nerves and reaches its maximum value

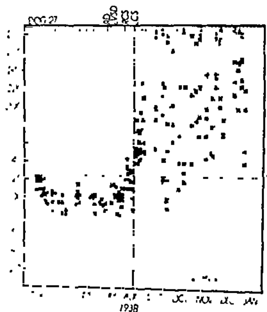

Fig. 12-11. Effect of the resection of the depressor nerves Diastolic pressure in millimeters of mercury. *RD*, resection of the right depressor nerve; *LVSD*, section of the left vagosympathetic trunk; *RCS*, section of the right carotid sinus, *LCS*, section of the left carotid sinus (*From Bedell Thomas, Bull Johns* Hopkins Hosp. 1944.)

between the second and fourth weeks The hypertension is accompanied by an increase of cardiac rate, the tachycardia usually being proportional to the elevation of pressure. Both the cardiac rate and the blood pressure present large fluctuations. Rest or sleep causes decrease of both, and may even produce normal levels On the other hand excitement or exertion increases considerably both the blood pressure and the cardiac rate. It is interesting to note these characteristics, which are different from those of renal hypertension, in which the pressure level is practically stable. Thoracic sympathectomy, including the stellate ganglia, normalizes the pulse rate but causes only a slight decrease in blood pressure This shows, on the one hand, that hypertension is not caused by the tachycardia and, on the other, that the tachycardia is mainly due to unopposed tonus of the cardioaccelerator center. Total sympathectomy prevents or abolishes almost completely the hypertension caused by section of the carotid and aortic nerves (Heymans and Bouckaert, 1935) Consequently, this type of hypertension seems to be due to an increase of sympathetic

tonus, secondary to the section of the depressor nerves. It is known that the tonus of the vasomotor center is inhibited by stimuli carried by the depressor nerves. When these stimuli are abolished, a hypertonus of the sympathetic center occurs, with subsequent hypertension and tachycardia.

The sudden and transitory increase of blood pressure which occurs immediately after the resection of the depressor nerves seems to be due, in part at least, to an increase of cardiac output, possibly resulting from a discharge of epinephrine by the adrenal medulla.

In the stage of chronic hypertension, some investigators have found vasoconstrictive activity in the blood, but this activity has been denied by others. The participation of epinephrine or norepinephrine has been assumed on account of the marked depressor effect which sympatholytic drugs exert in this condition. One of the most interesting phenomena is the latent period that exists between the section of the depressors and the onset of permanent hypertension. This has been attributed to an initial and transitory heart failure which is caused by the tachycardia and which would decrease cardiac output. Another theory explains this latent period as the necessary interval for the activation of some other pressor mechanism, according to this view the kidney contributes to the maintenance of the high level of pressure. The renal pressor mechanism could be activated by renal ischemia resulting from diffuse vasoconstriction or could be caused directly by impulses coming along the renal nerves. It has actually been shown that stimulation of the nerves of the renal pedicle can produce hypertension. Even though renal denervation does not cause a marked drop of blood pressure in these animals, the experiments of Grimson, Bouckaert, and Heymans (1939) have shown that the kidney plays a definite role in this type of hypertension. They found that if the entire sympathetic chain, except the renal innervation, is removed, there is a decrease of blood pressure but normal values are not reached. A subsequent resection of the renal nerves, on the other hand, completely normalizes the blood pressure. It seems that the hypertension is caused by sympathetic hypertonus directly acting on the vascular system and indirectly activating the renal pressor system.

Cerebral Ischemia. Nowak and Walker (1930) demonstrated that a ligature of the carotids, vertebrals, and spinal arteries made by subsequent steps in order to permit the establishment of collateral circulation, is followed by persistent hypertension in the dog. This has been subsequently confirmed in other species. The mechanism of this type of hypertension has not been much studied, but it seems reasonable to suppose that the hypertension, like that produced by cerebral compression, is caused by the effects of ischemia of the vasomotor center. This is stimulated and, by sending sympathetic impulses, causes diffuse vasoconstriction and increase of peripheral resistance. Bilateral compression of the carotid sinus area, including the external and internal carotids, produces persistent hypertension in the dog. Bilateral compression of the carotids *above* the sinus also causes hypertension (Wakerlin et al., 1954), giving the impression that the effect of carotid sinus compression may be attributed to cerebral ischemia. This hypertension is not associated with tachycardia.

10

The surgical correction of hypertension of renal vascular origin

JAMES A. HUNTER AND ORMAND C. JULIAN

The problem of arterial hypertension has been much investigated, with particular emphasis on the role of the kidney in its pathogenesis As long ago as 1836, Bright related hypertension to disease of the kidney Renal-related humoral mechanisms, renin and VEM (vasoexciter material), have been extensively studied in the laboratory, and their roles postulated Endocrine factors, particularly adrenal and thyroid gland relationships to hypertension, have been pursued. Goldblatt's demonstration (1934) that experimentally induced renal ischemia produces hypertension remains a most important contribution and, indeed, one of the best-known experimental works

Clinical observation and investigation have established a substantial list of pathologic states associated with hypertension, many of them related to renal disease. However, many patients with hypertension defy specific etiologic diagnosis and are considered to have "essential" or, perhaps better, "idiopathic" hypertension Despite important strides in the symptomatic medical treatment of elevated blood pressure, without regard to its cause, such management has numerous limitations and is not characterized by cure. On the contrary, hypertensive patients are cured, and the serious cardiac, renal, cerebral, vascular, and ocular sequelae arrested or prevented when a specific etiologic diagnosis can be made and corrective surgical measures applied.

The clinical importance of hypertensive disease of renovascular origin relates to the fact that in patients with blood pressure elevation due to such a cause, a specific diagnosis can be made and often a surgical cure effected.

Prior to the current decade, with its renewed interest in renovascular hypertension, there was an era of distinct disappointment and even skepticism regarding operative procedures for hypertension During this period, *nephrectomy* was applied for unilateral disease of the kidney, and the cure rates were not impressive, failing to exceed 26 per cent (Smith, 1948, 1952, Smithwick and Thomson). Improved understanding of the pathophysiology of renal hypertension, the availability of better diagnostic techniques, and the development of cardiovascular surgery with its technical skills, all have served to renew interest in this field and vastly to improve results

Lesions affecting the renal vessels that may result in secondary systemic hypertension include renal artery stenosis, renal arteriovenous fistula, renal artery occlusion, and aneurysm of the renal artery Hypertension results in the presence of such lesions because of the altered renal arterial flow or diminished arterial pulse pressure The importance of pulse pressure alterations in the production of renal hypertension has been demonstrated both clinically and experimentally (Morris et al, 1960a, Hawthorne et [illegible]

of [illegible]

zy[illegible]

pa[illegible] reactions involving a hepatic protein substrate and resulting in the formation

of a potent vasopressor substance (*angiotensin*).[1] The object of therapy is to restore, where possible, normal renal hemodynamics and relieve the hypertension.

RENAL ARTERY STENOSIS

After Goldblatt's original publication (1934), there appeared sporadic reports of hypertension due to renal artery stenosis. It remained, however, for the publication of Poutasse and Dustan (1957) to rekindle interest in this entity. More recently, numerous publications have been devoted to the subject and the total number of cases reported has rapidly increased.

Although by far the principal single cause of arterial stenosis is *focal arteriosclerotic disease*, there are multiple, less common causes The lesion may be congenital or acquired, with the former resulting in symptomatic hypertension during early childhood The varieties of nonarteriosclerotic stenosis include simple idiopathic congenital stenosis, stenosis due to fibromuscular hyperplasia (Wylie and Wellington), arteritis involving the renal arteries (Danaraj and Wong), syphilitic occlusion of the renal vessels (Price and Skelton), compression and stenosis of the arteries by malignant neoplasm (Blatt and Page), narrowing of a renal artery by a fibrous band (Imber and Clymer), distortion and narrowing of an artery by a hydatid cyst (Davson), compression of a renal artery by an aortic aneurysm (Hoffman), stenosis of the arterial orifice by a dissecting aneurysm (Case report M. G. H.), and renal arterial narrowing associated with coarctation of the abdominal aorta (Brust et al.)

The incidence of hypertension due to renal artery narrowing will relate to the index of suspicion of the physician. No age group is exempt, the diagnosis having been made in infants (De Camp and Birchall), as well as in adults in their eighth decade of life

The clinician's suspicions should be particularly aroused when the following clues are encountered. (1) significant hypertension in children or young adults in whom no other cause of secondary hypertension can be demonstrated; (2) hypertension of abrupt onset, (3) elevated blood pressure in patients with a history suggestive of renovascular accident; (4) severe hypertension that rapidly progresses to the malignant phase; (5) mild hypertension that suddenly becomes severe; (6) malignant hypertension in the older age group; (7) hypertension in a patient with known arteriosclerotic disease elsewhere in his vascular tree

Physical findings in patients with renal artery stenosis are seldom diagnostic. Although nonspecific, the cardiac and ocular sequelae of the pathologic blood pressure may be apparent and will reflect the physiologic importance of the hypertension. As is proper in all hypertensive patients, signs of coarctation of the aorta should be sought and proved absent. A careful bedside examination of the peripheral arterial system should be made to detect the smallest finding indicative of arteriosclerotic change. For example, a patient who has marked hypertension and one who has *a systolic bruit over an iliac artery* indicating the presence of arteriosclerotic disease may have similar involvement at the orifice of a renal artery. *Bruits over the renal area* have been uncommon in the authors' experience; when noted anteriorly, they are more often due to associated change in the aorta or iliac vessels. Careful auscultation should always be performed, both anteriorly and posteriorly, but one should realize that absence of the systolic bruit in no way excludes the diagnosis.

Routine investigations of the urinary tract are usually negative. Initial studies of the patient will include urinalysis, blood urea nitrogen or nonprotein nitrogen determination, chest x-ray, and electrocardiogram. Study of the urine will help to rule out renal parenchymal diseases such as nephritis that may result in hypertension Except in an infrequent patient with major bilateral narrowing of the renal arteries, there will be no azotemia. The electrocardiogram and roentgenogram will permit further definition of the cardiac sequelae of the hypertension.

The *intravenous pyelogram* deserves special mention

The technique of pyelography is altered in patients with hypertension, first films being obtained at 30 sec and 2 min, in addition to the customary 5-min study. An attempt is thus made to record the *nephrogram* and early appearance of the dye, so that bilateral function may be compared. Although it does not invariably do so, the kidney with arterial involvement may show a phase of delayed excretion on these early films Such a finding

[1] See Part 2, Chap. 27, for "physiology of renal circulation," and Chap 5, this Part, for the "humoral mechanism of hypertension" *Editor*

is of major importance, and is strong indication to proceed with studies as outlined below. A comparison of renal size is made from the x-rays Occasionally the involved kidney will be demonstrably *smaller* than its partner. Perhaps the most important comment to make in relation to the pyelogram is that in the classical instance of renovascular disease, this examination is normal Indeed, the greatest opportunities for cure lie in those patients who have essentially normal studies (Squire and Schlegel).

Specialized studies are then performed as indicated, to evaluate the hypertension further. These include the *radioisotope renogram*, differential studies of renal excretion, and *aortography* The use of ganglion-blocking agents, such as tetraethylammonium chloride, in diagnosis has not been helpful. The latter examination, when positive, is said to result in either a pressor response or in no fall in blood pressure (Brust and Ferris).

The simplest of the specialized examinations, the radioisotope renogram, is an excellent screening test to detect alterations in renal blood flow. The test is readily performed, the amount of irradiation received is minimal, and the cost is low.

Principally, the study involves the intravenous injection of a *radioisotope-tagged substance*, such as *Diodrast* or *Hippuran*, and then the recording of appearance and intensity at the renal areas. The gamma irradiation can be counted and charted in relation to time, and the two sides compared The initial peak of appearance relates directly to renal blood flow and, therefore, has particular importance

Most valuable in comparing the sides, when the normal kidney serves as a control, the results may be more difficult to evaluate when there is bilateral stenosis, and thus a symmetrically altered result. It is anticipated that this examination will come to be the main study utilized to screen candidates for aortography.

Work in the experimental laboratory by Mueller et al, H L White, and others has demonstrated that in renal ischemia, electrolyte excretion by the kidney is decreased In particular, *less sodium is excreted*, and the total volume output of that kidney is also diminished This principle, popularized by Howard et al (1954, 1956), is applied clinically in the use of split function studies when renal artery lesions are suspected The ureters are intubated, and urine collections are made in chemically clean glassware. Differential function studies, phenol sulphonphthalein excretions, and more complex clearance studies can then be performed as desired As with the radioisotope renogram, the most impressive results are obtained in patients with unilateral disease, when there is opportunity to contrast the sides. Reduction of volume excretion by 50 per cent and of sodium excretion by 15 per cent or more indicates a positive test (Connor et al). Shortcomings of this study include the necessity of *ureteral catheterization*, with the essential instrumentation and the possibility of inducing infection, technical difficulty relating to traumatic hematuria, leakage of urine about the collecting catheters, and the fact that results may not be definitive in bilateral disease, or even in unilateral disease. The data so obtained may be especially helpful in assisting in evaluation when aortography has led to the suspicion of a renal artery lesion

An operative prerequisite, and a necessary final examination before diagnosis can be conclusively established, is *aortography*. All the other studies, by virtue of their positive or negative results, reflect on the probability of there being a renovascular lesion. They are not, however, able to prove or disprove the diagnosis absolutely. The aortogram permits positive diagnosis, defines the anatomy of the lesion, directs the therapy, and permits speculation as to prognosis. One may consider the "work-up" of a person suspected of having renal arterial disease as proceeding in two phases: (1) preliminary studies, and (2) aortography.

In view of the importance of the aortogram in the final demonstration of the lesion, it is well to list the types of patient for whom arteriography is indicated.

1. Hypertensive patients who, when studied as outlined above, reveal data increasing the probability of a renal arterial lesion Anyone with a positive differential excretory study or radioisotope renogram should be subjected to aortography.

2. Young patients, certainly those under the age of 35, and especially children, in whom there is significant hypertension

3 Persons with established recent onset of blood pressure elevation

4 Patients with severe hypertension rapidly progressing to the malignant stage.

5 ...

...alignant hypertension.

6 Patients with demonstrable arteriosclerotic disease, especially of the aorta and iliac channels, plus hypertensive disease

7. Hypertensive patients with a history suggestive of a renovascular accident

8 A patient whose hypertensive disease is of progressive physiologic importance and who demands maximum study and therapy to alter an unfavorable prognosis

In the experience of the authors and of others aortography has been accomplished with little risk and with excellent results in terms of the data obtained

Two techniques are used (1) the translumbar percutaneous puncture of the aorta, (2) the retrograde method through a femoral artery With few exceptions, the *translumbar approach* is used in adults. Twenty to twenty-five milliliters of 70 per cent Urokon injected high in the abdominal aorta is usually adequate to outline the renal branches Simultaneous definition of iliac, femoral, and major lower extremity channels may be desirable in adults with arterial disease altering blood flow to the legs The main application of the *retrograde method* is in children, the authors have used it in children as a method of choice This approach may also be desirable in the occasional adult who is significantly ill, usually from cardiac complications of the hypertension, and in whom it is desirable to avoid the prone position with general anesthesia Using general anesthesia in children, and local anesthesia in adults, the femoral artery is exposed through a small skin incision, a transverse arterotomy performed in the common femoral artery, and the catheter passed proximally to the upper abdominal aorta Five to eight milliliters of 50 per cent contrast material will outline the aorta and its branches in a satisfactory manner in a child Perfection in technique is essential to either rule out the lesion with confidence or permit definition adequate to direct operative repair The procedure must be conducted technically in such a way as to shield and safeguard the operating personnel In the latter regard, adequate lengths of connecting tubing are a prerequisite to allow injection from behind a lead screen Ordinarily, the interpretation of the aortogram is not difficult Most commonly the narrowing will be noted at the origin of a single large renal artery. On occasion, the lesion occurs in a more distal portion of the artery, as is often the case when the etiologic factor is *fibromuscular hyperplasia Stenosis* may less commonly be seen in one of the secondary divisions of the main vessel Generally, a single film exposure on a 14 by 17 in cassette adequately records each injection When studying an unusual lesion, it may be necessary or desirable to use x-ray equipment that will permit multiple exposures during the single injection The authors have, for example, found this technique useful in studying a small hypertensive child whose kidneys were supplied by no less than six small arteries, precise definition of all six on a single film would have been difficult Most often, poststenotic dilatation is seen distal to the point of arterial obstruction, this finding confirming the presence of a true stenosis and differentiating it from artifact or spasm One may sometimes find indirect help in interpreting a questionable finding by reviewing the results of the differential excretion and radioisotope studies

During the past decade, the management of renovascular disease has undergone important changes. As this is an era of reconstructive vascular surgery, the principle has become one of repair rather than eradication of the involved part. Nevertheless, the surgeon is left a choice, except in bilateral lesions, of removing the involved kidney or of effecting an arterial repair The indications for reconstruction or nephrectomy thus merit review. The procedure of choice is restoration of normal renal arterial flow, for the following reasons·

1 In bilateral disease this is the only method available

2 A maximum of functional renal tissue is preserved.

3 The kidney supplied by the involved artery may be the better kidney of the two.

The latter statement is based on the *excellent evidence that stenosis protects the involved kidney from the impact of the hypertension it has produced, whereas there is no such mechanism to protect the contralateral organ*. Histologic studies from the two kidneys in instances of unilateral disease have shown significant arteriolar nephrosclerosis on the side with a normal arterial anatomy, and the absence of such changes on the side of arterial narrowing One would, therefore, anticipate that restoration of a normotensive state would most consistently follow bilateral renal arterial reconstruction, as both kidneys have been protected from the tension elevation, such has been found to be the case Patients with unilateral disease may have a slower response, or even an incomplete one, in terms of blood pressure reduction because of the perpetuating tendency of the arteriolar disease on the opposite side to maintain a pressure elevation It follows that, in all likelihood, a patient will be

encountered in whom the successful restoration of normal blood pressure will only follow *reconstruction of the narrowed artery and then nephrectomy* on the opposite side Such a case, to the authors' knowledge, has yet to be reported, but this would seem to be only a matter of time.

Nephrectomy is indicated (1) in the management of the anatomically unfavorable arterial lesion, such as that presenting several areas of stenosis in the patient with multiple small renal arteries, (2) in the treatment of the very ill patient with unilateral disease who is a grave surgical risk Fortunately, these two circumstances are infrequently encountered It is true that extraperitoneal nephrectomy is a simpler and more rapid procedure

A variety of methods and techniques of arterial reconstruction have been reported These include *endarterectomy* of the involved segment, *bypass graft* between aorta and renal artery distal to the stenosis, *longitudinal sectioning of the stenotic artery* and then *application of an onlay patch graft* to enlarge the circumference, *division of the artery with adjacent reimplantation*, and *splenorenal arterial anastomosis*

length by carrying the dissection outward from their aortic origin If exposure of the distal divisions of the artery is desired, improved access may be gained with extraperitoneal dissection, beginning at the paracolic gutter laterally. Although exposure of the origin of the renal artery and its proximal main trunk is the easiest method, by combining these two medial and lateral approaches, any portion of the extranephric vessel may be achieved As most of the stenoses occur at the proximal end of the renal artery, exposure in the average case is not hard to achieve The narrowed segment is then examined and the distal, generally dilated, segment is palpated to elicit the presence of a thrill or diminished pressure. It is desirable at this point to determine pressures proximal and distal to the obstruction and to establish *the gradient* that it has produced. The character of the proximal renal artery or aorta, and also of the distal vessel, is then evaluated and the method of surgical repair decided upon. In children, one is very much more restricted in the selection of a method of reconstruction because of the necessity of avoiding the use of prosthetic materials. This is especially so in very small children who have a major growth potential Wherever possible in the pediatric age group, the principle of *resection of* [illegible]

Even though the period of renal artery occlusion required for repair has usually been less than 15 min, the authors subject their patients to *systemic hypothermia* [2] for added safety

Regardless of which reconstructive technique is to be employed, the surgical approach of preference is anterior and transperitoneal A generous midline or paramedian incision is used The transverse incision, or flank approach, has been found to be less desirable After the peritoneal cavity has been entered and explored, the transverse colon and omentum are lifted up and out of the wound, and placed on the anterior thorax The small bowel is similarly eviscerated and packed off to the right The latter maneuver may be facilitated, and exposure about the renal arteries later enhanced, by division of the ligament of Treitz The abdominal aorta is then exposed by incising the posterior peritoneum in the avascular area between the root of the small bowel mesentery on the right and the inferior mesenteric vein on the left. The dissection is then carried proximally until the left renal vein and the renal arteries are identified It is helpful at this point to use the previously performed aortogram for direction in terms of the number and locale of the individual renal vessels It is possible to expose the main renal arteries throughout their

[2] See Part 6, Chap 16 Editor

[illegible] aorta, should be used.

Arterial anastomoses are performed using fine sutures and interrupted technique. In the repair of a renal artery in a 4-year-old, where the stenosis involved too long a segment for use of the two previously mentioned techniques, the authors have used *longitudinal section* and then the *placement of an onlay autogenous venous graft* to provide for a normal lumen The portion of vein was obtained from the patient's internal iliac system

In the treatment of adult stenosis, where the etiologic factor is most commonly focal arteriosclerotic change, the method of choice is either *endarterectomy or division of the vessel distal to the stenosis, and reimplantation on the adjacent aortic wall* These techniques are best suited to the patient with a localized process involving the immediate area of the arterial origin and with a thin-walled, normal adjacent aorta Because the aorta is generally thickened and abnormal in the entire general area of the renal vessel, the alternate reconstruction technique of *bypass grafting* has been used most commonly.

If reconstructive surgery is to be performed in relation to the abdominal aorta itself, as in the management of aortoiliac occlusive disease or arteriosclerotic abdominal aneurysm, then the bypass technique becomes by far the most practical Cus-

6 Patients with demonstrable arteriosclerotic disease, especially of the aorta and iliac channels, plus hypertensive disease

7. Hypertensive patients with a history suggestive of a renovascular accident.

8 A patient whose hypertensive disease is of progressive physiologic importance and who demands maximum study and therapy to alter an unfavorable prognosis

In the experience of the authors and of others aortography has been accomplished with little risk and with excellent results in terms of the data obtained

Two techniques are used (1) the translumbar percutaneous puncture of the aorta, (2) the retrograde method through a femoral artery With few exceptions, the *translumbar approach* is used in adults. Twenty to twenty-five milliliters of 70 per cent Urokon injected high in the abdominal aorta is usually adequate to outline the renal branches Simultaneous definition of iliac, femoral, and major lower extremity channels may be desirable in adults with arterial disease altering blood flow to the legs The main application of the *retrograde method* is in children, the authors have used it in children as a method of choice This approach may also be desirable in the occasional adult who is significantly ill, usually from cardiac complications of the hypertension, and in whom it is desirable to avoid the prone position with general anesthesia Using general anesthesia in children, and local anesthesia in adults, the femoral artery is exposed through a small skin incision, a transverse arterotomy performed in the common femoral artery, and the catheter passed proximally to the upper abdominal aorta. Five to eight milliliters of 50 per cent contrast material will outline the aorta and its branches in a satisfactory manner in a child Perfection in technique is essential to either rule out the lesion with confidence or permit definition adequate to direct operative repair. The procedure must be conducted technically in such a way as to shield and safeguard the operating personnel In the latter regard, adequate lengths of connecting tubing are a prerequisite to allow injection from behind a lead screen Ordinarily, the interpretation of the aortogram is not difficult Most commonly the narrowing will be noted at the origin of a single large renal artery On occasion, the lesion occurs in a more distal portion of the artery, as is often the case when the etiologic factor is *fibromuscular hyperplasia Stenosis* may less commonly be seen in one of the secondary divisions of the main vessel Generally, a single film exposure on a 14 by 17 in cassette adequately records each injection. When studying an unusual lesion, it may be necessary or desirable to use x-ray equipment that will permit multiple exposures during the single injection The authors have, for example, found this technique useful in studying a small hypertensive child whose kidneys were supplied by no less than six small arteries, precise definition of all six on a single film would have been difficult Most often, poststenotic dilatation is seen distal to the point of arterial obstruction, this finding confirming the presence of a true stenosis and differentiating it from artifact or spasm. One may sometimes find indirect help in interpreting a questionable finding by reviewing the results of the differential excretion and radioisotope studies

During the past decade, the management of renovascular disease has undergone important changes As this is an era of reconstructive vascular surgery, the principle has become one of repair rather than eradication of the involved part. Nevertheless, the surgeon is left a choice, except in bilateral lesions, of removing the involved kidney or of effecting an arterial repair. The indications for reconstruction or nephrectomy thus merit review. The procedure of choice is restoration of normal renal arterial flow, for the following reasons.

1 In bilateral disease this is the only method available

2 A maximum of functional renal tissue is preserved

3 The kidney supplied by the involved artery may be the better kidney of the two

The latter statement is based on the *excellent evidence that stenosis protects the involved kidney from the impact of the hypertension it has produced, whereas there is no such mechanism to protect the contralateral organ.* Histologic studies from the two kidneys in instances of unilateral disease have shown significant arteriolar nephrosclerosis on the side with a normal arterial anatomy, and the absence of such changes on the side of arterial narrowing One would, therefore, anticipate that restoration of a normotensive state would most consistently follow bilateral renal arterial reconstruction, as both kidneys have been protected from the tension elevation, such has been found to be the case Patients with unilateral disease may have a slower response, or even an incomplete one, in terms of blood pressure reduction because of the perpetuating tendency of the arteriolar disease on the opposite side to maintain a pressure elevation. It follows that, in all likelihood, a patient will be

hypertension following nephrectomy for obvious fistula, but did for the first time postoperatively respond to hypertensive drugs. It is considered likely that the opposite kidney, by virtue of its arteriolar change secondary to the hypertension, is perpetuating the blood pressure elevation

RENAL ARTERY ANEURYSM

Aneurysms of the renal artery are not common. The literature records an incidence of 0.1 to 0.15 per cent based on autopsy studies, or 1 per cent of all aneurysms (Ippolito and LeVeen). The total number of cases reported as of 1959 by Glanton and associates was 143. The lesion may be secondary to arteriosclerosis, trauma, infection, or a congenital defect of the arterial wall, and may be classified as a true or false aneurysm The majority of the aneurysms are saccular in type. The post-stenotic dilatation, typically present distal to an arterial stenosis, should not be classified as an aneurysm, the anatomic and physiologic features are obviously entirely different Case reports have shown no predilection concerning sex of the patient or side of involvement Lesions have been reported from childhood through advanced age, but most of them have been diagnosed in the 40- to 60-year-old group. The aneurysm may occur in the main renal artery, in the renal parenchyma, or at any point between, but most of them occur in the distal main channel or just beyond the primary bifurcation (McLelland)

A survey of the literature reveals that flank pain and hematuria are the most common symptoms Hypertension occurs in only 15 to 20 per cent of patients, and in some instances there may be no relationship between the aneurysm and the pressure elevation A palpable mass will be noted in about 25 per cent of patients, and microscopic, if not gross, hematuria can be detected in about 35 per cent.

Complications of renal artery aneurysm include rare instances of renal infarction and, more commonly, rupture The rupture may be into adjacent retroperitoneal tissues with a high immediate mortality, or into the adjacent vein with the resulting complication of renal arteriovenous fistula

Although of the reported cases many were [illegible] often seen with splenic artery aneurysms, may be seen on the plain x-ray films. Unfortunately, less than one-third of the lesions present this finding (Pastor). The pyelogram may show distortion of the kidney, and direct evidence of renal artery abnormality will be demonstrated on the aortogram.

Treatment, with few exceptions, has been *nephrectomy*. The opportunity of resection and reconstruction with renal preservation should be taken advantage of when there is a technically favorable lesion in the main renal artery If the aneurysm has been obstructing the arterial flow and hypertension has resulted, a favorable result in terms of blood pressure can be anticipated. It should be remembered, however, that often lesions do not produce hypertension, and that elevated blood pressure may not be due to the aneurysm. The data would indicate caution in relating hypertension to a given renal artery aneurysm, and, therefore, conservatism in predicting its relief by surgical eradication of the lesion

RENAL ARTERY THROMBOSIS

Thrombosis of a renal artery may occur secondary to *preexisting local* disease in the ultimately occluded channel, or may be due to an *embolic phenomenon* (Ben-Asher, Fishberg). *Total infarction of the kidney* does not result in hypertension, but *subtotal infarction* or *ischemia* may give rise to malignant hyperten- [illegible] per cent of patients, *occult* or frank hematuria. Renal infarction may be unilateral, *bilateral*, total, or segmental

Diagnosis of the acute lesion will be directed *by the onset of acute flank pain*, the finding of *hematuria, and often* leucocytosis. Intravenous pyelography will show variable results [illegible] retrograde pyelogram should be normal The diagnosis of renal arterial occlusion should be *made possible* in most cases by a carefully *performed* aortogram.

When *hypertension* results from the renal *ischemia, relief* from surgery *may* be anticipated, as in the patient of Wilkey and associates Treatment will usually consist of nephrectomy for main renal artery thrombosis, or of subtotal *resection* for partial ischemia.

hypertension following nephrectomy for obvious fistula, but did for the first time postoperatively respond to hypertensive drugs. It is considered likely that the opposite kidney, by virtue of its arteriolar change secondary to the hypertension, is perpetuating the blood pressure elevation.

RENAL ARTERY ANEURYSM

Aneurysms of the renal artery are not common. The literature records an incidence of 0.1 to 0.15 per cent based on autopsy studies, or 1 per cent of all aneurysms (Ippolito and LeVeen). The total number of cases reported as of 1959 by Glanton and associates was 143. The lesion may be secondary to arteriosclerosis, trauma, infection, or a congenital defect of the arterial wall, and may be classified as a true or false aneurysm. The majority of the aneurysms are saccular in type. The poststenotic dilatation, typically present distal to an arterial stenosis, should not be classified as an aneurysm, the anatomic and physiologic features are obviously entirely different. Case reports have shown no predilection concerning sex of the patient or side of involvement. Lesions have been reported from childhood through advanced age, but most of them have been diagnosed in the 40- to 60-year-old group. The aneurysm may occur in the main renal artery, in the renal parenchyma, or at any point between, but most of them occur in the distal main channel or just beyond the primary bifurcation (McLelland).

A survey of the literature reveals that flank pain and hematuria are the most common symptoms. Hypertension occurs in only 15 to 20 per cent of patients, and in some instances there may be no relationship between the aneurysm and the pressure elevation. A palpable mass will be noted in about 25 per cent of patients, and microscopic, if not gross, hematuria can be detected in about 35 per cent.

Complications of renal artery aneurysm include rare instances of renal infarction and, more commonly, rupture. The rupture may be into adjacent retroperitoneal tissues with a high immediate mortality, or into the adjacent vein with the resulting complication of renal arteriovenous fistula.

Although of the reported cases many were not diagnosed [illegible]
should

often seen with splenic artery aneurysms, may be seen on the plain x-ray films. Unfortunately, less than one-third of the lesions present this finding (Pastor). The pyelogram may show distortion of the kidney, and direct evidence of renal artery abnormality will be demonstrated on the aortogram.

Treatment, with few exceptions, has been *nephrectomy*. The opportunity of resection and reconstruction with renal preservation should be taken advantage of when there is a technically favorable lesion in the main renal artery. If the aneurysm has been obstructing the arterial flow and hypertension has resulted, a favorable result in terms of blood pressure can be anticipated. It should be remembered, however, that often lesions do not produce hypertension, and that elevated blood pressure may not be due to the aneurysm. The data would indicate caution in relating hypertension to a given renal artery aneurysm, and, therefore, conservatism in predicting its relief by surgical eradication of the lesion.

RENAL ARTERY THROMBOSIS

Thrombosis of a renal artery may occur secondary to preexisting local disease in the ultimately occluded channel, or may be due to an *embolic phenomenon* (Ben-Asher, Fishberg). *Total infarction of the kidney* does not result in hypertension, but *subtotal infarction* or *ischemia* may give rise to malignant hypertension, which may ultimately cause death. Classically, the onset is marked by flank pain, hypertension, and, in approximately 50 per cent of patients, occult or frank hematuria. Renal infarction may be unilateral, bilateral, total, or segmental.

Diagnosis of the acute lesion will be directed by the onset of acute flank pain, the finding of hematuria, and often leucocytosis. Intravenous pyelography will show variable results, depending upon the total degree of infarction, but often there will be nonvisualization. Initially the retrograde pyelogram should be normal. The diagnosis of renal arterial occlusion should be made possible in most cases by a carefully performed aortogram.

When hypertension results from the renal ischemia, relief from surgery may be anticipated, as in the patient of Wilkey and associates. Treatment will usually consist of nephrectomy for main renal artery thrombosis, or of subtotal resection for partial ischemia.

PART 13

Pulmonary hypertension and pulmonary heart disease (cor pulmonale)

1

Pathology of chronic cor pulmonale

DAVID M. SPAIN

A strict definition of chronic cor pulmonale limits it to *that form of hypertrophy of the right side of the heart (with or without congestive failure) that develops secondary to diseases of the lung, pulmonary blood vessels, chest cage, or primary pulmonary hypertension* A wider use of the term includes *those forms of pulmonary hypertension that occur secondary to mitral stenosis and certain forms of congenital heart disease*. The development of all forms of chronic cor pulmonale is mainly dependent upon the degree and duration of the elevation of the pressure in the pulmonary vascular bed Therefore, the term *pulmonary hypertensive heart disease* is preferable Many classifications have been proposed for chronic cor pulmonale None fulfill all the basic pathogenetic, functional, and clinical needs because gaps in our knowledge still exist concerning the relative importance of neurohumoral, structural, and functional mechanisms in the control of vasomotor tone and blood flow in the pulmonary vascular bed

The proper appreciation of pulmonary hypertension requires knowledge not only of those alterations in the lungs, pulmonary vessels, heart, and associated structures that precede the onset of the hypertension, but also of the changes in the heart, pulmonary blood vessels, and other viscera that occur as sequelae to the effects of the hypertension

THE PULMONARY VASCULAR BED

The pulmonary arterial system is divided into four major segments. The largest vessels are the *elastic arteries*, with an external diameter usually greater than 1,000 μ The walls of these arteries contain considerable elastic tissue and smooth muscle. The next category is comprised of the *muscular arteries*, with a luminal range of 1,000 to 100 μ in diameter. Their walls are composed of a circular muscular layer enclosed in internal and external elastic membranes The next smaller segments are the *arterioles*, which run a very short course and do not contain muscle. These are usually less than 100 μ in diameter The walls consist of an endothelial layer supported by a single elastic membrane. Finally, there are the *capillaries*, which have neither muscle nor elastic tissue and consist of endothelium surrounded by basement membrane. It is of significance that the muscular arteries, which are the main resistance vessels, have only a very thin muscular coat For this reason, the vasomotor, reflex, or other functional influences on the muscular coat can play only a relatively small part in increasing resistance to the flow of blood and consequently in the production of pulmonary hypertension. Therefore, *mechanical and other functional factors are more important in controlling the pressure in the pulmonary arterial system than is the case in the systemic circulation* The interplay of these mechanical and functional factors, however, is complex. Thus, several characteristics of the pulmonary vascular bed serve to distinguish it from the systemic vascular bed and also influence the significance of the anatomic alterations secondary to pulmonary disease. *These are its great distensibility, large reserve, and thin musculature.* These features contribute to the maintenance of the pulmonary vascular bed as a low-pressure system. Pulmonary

hypertension, the basic functional cause for the development of cor pulmonale, differs from systemic hypertension in that it is possible, in the overwhelming majority of instances, to identify some underlying organic alterations that serve to explain rationally the pathogenesis of the increase in blood pressure. In systemic hypertension, mainly because of the well-developed musculature in the arteriolar system and its response to a wide variety of neurohumoral mechanisms and agents, organic alterations that serve to explain the process rationally are less frequently encountered

POST-MORTEM IDENTIFICATION OF COR PULMONALE

The recognition of cor pulmonale at autopsy is almost entirely dependent upon the evaluation of the degree of *hypertrophy of the right ventricular myocardium.* The right ventricle at birth has a relatively greater muscle mass than the left because in utero the pulmonary circulation is maintained as a high-resistance system for the purpose of shunting the blood of the right side of the heart away from the lungs into the systemic circulation via the ductus. After birth, upon closure of the foramen ovale and ductus arteriosus, the ventricular relationships are altered, so that in adult life, the left ventricle contains the preponderance of muscle mass Ordinarily, in the adult, *any excess in diameter of the right ventricular wall over 5 mm is regarded as hypertrophy* The evaluation of this hypertrophy as being entirely the result of pulmonary hypertension is usually dependent upon the elimination of other causes of cardiac hypertrophy such as systemic hypertension (with chronic left ventricular failure), valvular disease, myocarditis, nutritional defects, etc However, the simple determination of the thickness of the right ventricle in itself as the means of diagnosing cor pulmonale at post-mortem examination is sometimes inadequate. If this measurement is the only consideration, then a number of cases will be missed. A more exact and inclusive method is to weigh the left ventricle with the attached septum separately from the right ventricle after dissection made according to the technique described by Fulton et al. Consideration must also be given to the effects of dilatation of the heart on the thickness of the ventricle, and also to debilitating disease process, in which the heart mass as a whole may be reduced in weight. Because of the variations in the anatomic methods for the determination of cor pulmonale, differences exist in the reported incidence of this condition, even when diseases with the same underlying pulmonary diseases are studied. The condition of the pulmonary vasculature may be helpful, but correlation between these changes and the degree of right-sided heart hypertrophy is variable.

CLASSIFICATION OF CAUSES OF PULMONARY HYPERTENSION

Pulmonary hypertension is classified as *primary or secondary.* In *primary hypertension*, the mechanisms are unknown, and well-authenticated cases in adults are rare (see Causes of Pulmonary Hypertension, below). In adults, most forms of pulmonary hypertension occur secondary to diseases of the chest cage, lungs, or pulmonary vessels (see Classification of Pulmonary Disease—Causes of Chronic Cor Pulmonale, below). A modified functional classi-

Causes of Pulmonary Hypertension

- I Primary pulmonary hypertension (pathogenesis unclear)
  - *A* Childhood type
  - *B* Adult type
- II Secondary pulmonary hypertension
  - *A* Congenital heart disease with left-to-right shunts
  - *B* Acquired heart disease (mitral stenosis)
  - *C* Pulmonary disease
    - 1 Chest cage and pleura (kyphoscoliosis, thoracoplasty)
    - 2 Parenchymal disease (emphysema, interstitial fibrosis)
    - 3 Pulmonary vascular disease (thromboembolism, schistosomiasis)

Classification of Pulmonary Disease—Causes of Chronic Cor Pulmonale

- I Anatomic or functional alterations in thoracic cage
  - *A* Kyphoscoliosis, thoracoplasty
  - *B* Obesity syndrome
  - *C* Fibrous pleural envelope
- II Anatomic alterations in the pulmonary vasculature
  - *A* Main pulmonary arteries (thrombus, extrinsic pressure)
  - *B* Muscular arteries and arterioles (thromboembolism, arteritis, schistosomiasis)
  - *C* Anomalies, malformations, or tumors of pulmonary vessels
  - *D* Venous obstruction
- III Anatomic alterations in the bronchi and pulmonary parenchyma
  - *A* Idiopathic, primary, or large-lung emphysema
  - *B* Secondary obstructive emphysema (bronchiectasis, pneumoconiosis, asthma, tuberculosis)
  - *C* Diffuse interstitial inflammation and fibrosis (sarcoid, beryllhosis, interstitial fibrosis)

fication suggested by Mack subdivides cor pulmonale caused by pulmonary disease into two main groups, *type 1*, in which the pulmonary diseases are associated with *chronic diffuse obstructive emphysema*, and *type 2*, in which the pulmonary diseases also contain *pathologic processes localized in or about the blood vessels*. It is also recognized that there may be no rigid distinction between the two groups, in that the features of both may be present in any individual case. The significance of this classification is that in hypertension associated with pulmonary disorders, some of the underlying disturbances may be reversible, whereas in the type based on organic changes of the vasculature, reversibility is rare.

The mechanisms by which congenital heart disease leads to pulmonary hypertension are related basically to persistent communications between the pulmonary and systemic circuits, usually with a left-to-right shunt. In these situations, abnormal alterations exist in pressure and flow relationships. These vary with the type of congenital malformation and the underlying state of the pulmonary vascular bed. The relative importance of flow as related to pressure changes in the production of the pulmonary hypertension is as yet not entirely resolved. In rheumatic mitral stenosis, there is the additional factor of an increase in left atrial pressure, which increases the distending pressure in the various pulmonary vessels. However, no linear correlation exists between the degree and duration of the mitral stenosis, the level of pressure in the pulmonary circuit, and the secondary changes in the pulmonary vessels.

PULMONARY MECHANISMS THAT PRODUCE HYPERTENSION

In pulmonary disease, those structural alterations of the pulmonary vascular bed that are of primary significance consist of varying degrees of obstruction, compression, and obliteration of the capillary bed in ventilated lungs, luminal narrowing, occlusion, or distortion of the smaller muscular pulmonary arteries, precapillary arterioles, and veins; and changes in the immediate tissue environment of the vessels, which tend to alter transmural pressure and thus diminish distensibility of the vessels. The distensibility potential, large reserve, and relative lack of musculature of the pulmonary vascular bed are key factors in the proper evaluation of the relative effects of structural versus functional alterations in the production of pulmonary hypertension.

The primary lung diseases that affect the pulmonary vascular bed are numerous. A study of over 10 years ago reported the findings of 100 consecutively autopsied cases of cor pulmonale and revealed the incidence of underlying "primary" pulmonary disease shown in Table 13-1. More recent studies of consecutively autopsied cases of cor pulmonale reveal that *idiopathic, obstructive, or large lung emphysema has become absolutely and relatively the most important cause of cor pulmonale, whereas bronchiectasis, a disappearing disease, has decreased as an underlying pulmonary mechanism.*

The significance of pulmonary tuberculosis as a cause of cor pulmonale is difficult to evaluate, since the types of cases vary from one institution to another. In recent years, the chronic forms of tuberculosis have declined, and consequently the long-standing cases with fibrosis and secondary emphysema are not seen so frequently. In past years, the incidence of cor pulmonale in tuberculosis was related to the healing process, with emphysema produced as a consequence of fibrosis in areas of widespread bronchogenic dissemination.

There is no direct relationship between cor pulmonale and the degree of parenchymal destruction. In certain areas of the country, in-

TABLE 13-1 BASIC UNDERLYING PULMONARY CONDITIONS IN 100 CONSECUTIVE NECROPSIES ON PATIENTS WITH COR PULMONALE

Underlying pulmonary condition	*No of cases*

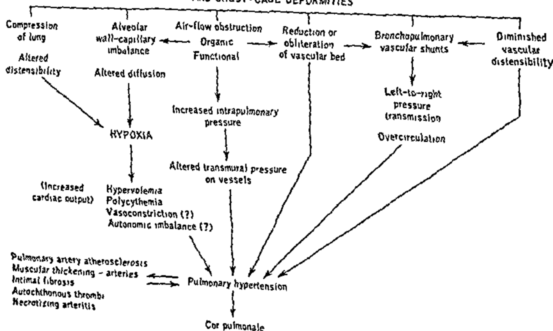
Scleroderma. . . .	1
Boeck's sarcoid	2

dustrial dust exposures and pneumoconiosis are of great importance as causes of cor pulmonale. There appears to be an increase in the incidence of diffuse interstitial inflammation and fibrosis of the lung. In some of these cases, cor pulmonale occurs.

In the preantibiotic period, a study of 200 consecutive autopsied cases of *bronchiectasis* that had not been treated with surgery revealed that in 38 cases, the bronchiectasis was bilateral and diffuse, and involved the smaller ramifications of the bronchial tree. Twenty-five of these 38 cases had hypertrophy of the right ventricle. In none of the other cases was cor pulmonale noted. This would indicate that *pulmonary disease usually must be diffuse and bilateral in order to produce significant structural alterations in the pulmonary vascular bed that will eventuate in cor pulmonale.* In these 25 cases, it is important to note that *emphysema* was a prominent feature. Liebow et al. (1949) demonstrated *large bronchopulmonary arterial communications* in advanced bronchiectasis. These shunts, which allow a high-pressure system to communicate with a low-pressure system, are probably not of prime importance in the causation of pulmonary hypertension because, as already noted, cor pulmonale does not occur in bronchiectasis unless the process is widespread and accompanied by emphysema.

Notably absent from the list of pulmonary conditions that cause cor pulmonale are those which produce solid areas of carnification or organization of varying portions of the parenchyma of the lung (organized pneumonia, radiation pneumonitis with fibrosis, lipoid pneumonia, etc.). Although structural alterations of the pulmonary vascular bed in such areas are profound, the fact that there is no parenchymal function (ventilation) present renders these changes of little clinical or physiologic significance. The granulation tissue in these areas is mostly supplied by the bronchial arterial system, and any alteration in flow would not be reflected in the pulmonary circuit. Only in those cases where the anatomic extent of lung involvement is so great as to deplete the vast reserve of the pulmonary vascular bed, are clinical or abnormal physiologic manifestations present. It should be noted that, provided the contralateral lung is normal, pneumonectomy does not produce a significant rise in pulmonary pressure.

The most important and basic underlying pulmonary disease that compromises the pulmonary circulation is emphysema. This includes the so-called primary, idiopathic, or large-lung type, the pathogenesis of which is still in dispute, as well as the forms of obstructive emphysema that are secondary to other primary pulmonary disease such as bronchial asthma, silicosis, etc. Anatomically, it is difficult, if not in most instances impossible, to recognize emphysema definitively unless it has entered the destructive phase, in which *the alveolar walls are disrupted, with coalescence of the alveolar spaces.* This alteration of the alveolar walls is the key to the morphologic alterations in the pulmonary vascular bed in emphysema. The alveolar walls are destroyed, thinned, disrupted, and at times thickened with fibrous tissue, inflammatory exudate, or an increase in smooth muscle. These alterations directly affect the capillary bed, as well as some of the larger vessels (veins and arteries).



Difficulties in quantitatively measuring changes in the capillary bed are numerous. The techniques that are so advantageously applied to the study of the larger vessels and bronchopulmonary communications require injection pressures so high as to make them unrealistic for the study of the capillary bed. Furthermore, it is difficult to simulate the intraalveolar pressure relationships that exist during life. However, some information can be gained from a poor substitute, and that is the study of hyperemic or congested emphysematous lungs at post mortem in the human being. It should be remembered that studying sections of the lung in this way, relative to pressure, flow, and ventilatory interrelationships, is analogous to studying one flat still film in a three-dimensional motion picture. Yet, despite the errors and limitations inherent in such a study, it is possible to demonstrate certain alterations and abnormal relationships.

In comparison with the congested normal lung, there is *a diminution in the number of hyperemic capillaries in many areas of the emphysematous alveolar walls.* In the normal lung, the distribution of the congested capillaries is regular, whereas in emphysema it is irregular. A relatively larger number of precapillary arterioles and smaller arteries is seen in the alveolar walls. Some of these thin-walled distended vessels may even be capillaries. Thus, many of the red blood cells passing

through these vessels in the alveolar walls are now quite distant from the alveolar capillary interface. In the normal lung, the capillaries usually are only distended to the caliber of the diameter of one red blood cell The inclusion of terminal bronchiolar passages in the distended emphysematous spaces accounts for the incorporation of greater numbers of larger vessels in the walls of the emphysematous air sacs Many of the capillaries (distended or not) are removed from intimate contact with the alveolar interface by fibrous tissue, smooth muscle, or inflammatory exudate To make the situation more complex, seemingly adequately perfused alveolar walls may exist in areas where, from a structural point of view, there would appear to be insufficient ventilation In contrast, one may observe meager perfusion in alveoli that would appear to have been better ventilated This is partly the consequence of the varied interplay of mechanical alterations which, in some areas, distend portions of the lung and, in others, may partially compress adjacent pulmonary parenchyma Also present are elongation, distortion, and compression of the larger vessels (veins and arteries) that course through the emphysematous areas These in turn may be supplying or draining capillaries in areas of pulmonary parenchyma that are relatively normal The variety of these changes is great from one portion of the lung to another and exists even in the smaller pulmonary subunits Variation and lack of homogeneity are characteristic This condition of *varied alveolar wall–capillary imbalance* is one of the basic consequences of the structural alterations that occur in emphysema The implications of this, relative to proper interpretation and evaluation of various function tests, are obvious

In addition to the direct anatomic alterations on the capillary, arteriolar, and small arterial and venous bed, the indirect effects of the altered pressure relationships that occur in the environment of these vessels as a consequence of emphysema have serious implications In emphysema, as well as in other pulmonary conditions, profound effects on function (hypoxia, etc.) alter the pulmonary blood flow, volume, and tension well in advance of the destructive effects of the disease on the morphologic characteristics of the vascular bed.

The relative importance of the *direct structural* versus the *indirect functional effects* on the pulmonary circulation may be illustrated by such conditions as kyphoscoliosis, complete unilateral thoracoplasty, and the obesity syndrome In these conditions, in time, pulmonary hypertension develops which may be severe enough to produce cor pulmonale, yet in some cases of kyphoscoliosis as well as in unilateral thoracoplasty, the emphysema and the struc-

tural changes in the blood vessels are entirely inadequate to account for the cor pulmonale. In the obesity syndrome, of course, there is no emphysema or any other notable primary structural alteration in the pulmonary vascular bed. Situations of this sort indicate that such factors as hypoxia, hypervolemia, etc., are perhaps the primary factors in the development of pulmonary hypertension rather than the structural alterations that develop later—in the destructive and irreversible phases of pulmonary disease processes. In *kyphoscoliosis* and in *unilateral thoracoplasty*, unilateral kinking of vessels is probably not a factor because the secondary vascular manifestations of pulmonary hypertension are equally reflected in both lungs.

In an entirely different area of lung disease, *the diffuse interstitial, inflammatory, and fibrotic processes*, cor pulmonale also occurs. In this group, which includes nonspecific interstitial fibrosis, berylliosis, sarcoid, certain forms of pneumoconiosis, etc., the blood vessels throughout the lung are encased in an environment of fibrous tissue, inflammatory exudate, granulomas, and edema. This reduces the distensibility of the vascular bed. The alveolar-capillary block and diminished ventilation of the lung in these conditions contribute important functional disturbances that favor the onset of pulmonary hypertension.

A general scheme of the pathogenesis of pulmonary hypertension in pulmonary disease is presented in the diagram, "Pathogenesis of Cor Pulmonale in Chronic Pulmonary Disease and Chest-cage Deformities" (page 13-7).

CHANGES IN THE VASCULAR BED

Direct structural involvement of the pulmonary arterial system by *thrombi, embolic carcinoma, polyarteritis*, or *schistosomiasis* obviously increases the resistance to the flow of blood. Plexiform vascular arrangements have been observed in these conditions, similar to those noted in pulmonary hypertension secondary to congenital cardiovascular disease. Whether these plexiform vascular arrangements are bypasses, vascularized granulation tissue, or shunts is not always entirely clear.

In cor pulmonale, the most consistent and prominent morphologic changes in the pulmonary vascular bed are actually secondary manifestations to the alterations in blood flow, volume, and tension produced by the various causes of chronic cor pulmonale. These changes consist basically of *atherosclerosis in the larger elastic arteries, hypertrophy (or at least apparent thickening) and the development of a longitudinal muscle layer of the muscular arteries, and fibrosis of the intima in the smaller arteries and precapillary arterioles*. The evaluation of muscular thickening is difficult because of the artifact produced by contraction.

Other changes consist of autochthonous *arterial thrombi* and *necrotizing arteritis or arteriolitis*. These thrombi may become so unrecognizable through organization as to be confused with arteriosclerosis (Fig. 13-1).

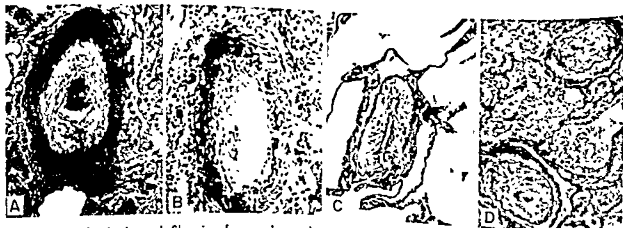


Fig. 13-1. A. Intimal fibrosis of muscular pulmonary artery (secondary to pulmonary hypertension). B. Necrotizing lesion in muscular pulmonary artery in a case of advanced mitral stenosis. C. Muscular thickening of a small muscular artery in a case of emphysema with pulmonary hypertension. D. Canalized and organized thrombi in muscular pulmonary arteries.

This has unfortunately led to the erroneous classification of some cases as primary pulmonary hypertension. The necrotizing vascular lesions in the past have been misinterpreted as specific consequences of rheumatic fever but more recently are regarded as one of the nonspecific effects of high pressure on the pulmonary vascular circuit. These alterations in turn may contribute to the increased vascular resistance to blood flow.

In pulmonary hypertension associated with congenital heart disease, the severity of the changes in the pulmonary blood vessels parallels the degree of pulmonary hypertension. In contrast to this, in pulmonary hypertension caused by lung disease in adults, there is poor approximation between the severity of the hypertension and the extent of the secondary vascular changes. Care must be taken not to confuse morphologic alterations in the arteries as a result of aging with those specifically caused by hypertension.

In the adult, the average weight of the heart in autopsied cases of chronic cor pulmonale is 450 Gm, with variations between 350 and 800 Gm. The average thickness of the right ventricular wall is 0.8 cm, with extremes of 0.6 and 1.5 cm. The left ventricle, at times, may exhibit a minimal to moderate degree of hypertrophy that cannot be related to other diseases. This may be partially explained by the effects of hypoxia on the heart and possibly by the appearance of large bronchopulmonary venous shunts in emphysema (see Chap. 3). Fibrosis of the myocardium is not a prominent feature and, when present, can usually be accounted for on the basis of a frequently coexistent coronary atherosclerosis. Mural thrombi are occasionally present in the right atrium. Also, in some instances, there may be notable dilatation of the tricuspid valve ring.

When failure occurs in chronic cor pulmonale, the liver and spleen are the constant sites of varying degrees of both acute and chronic congestion. Cardiac cirrhosis of the liver, although generally uncommon, occurs more frequently in this than in other forms of heart failure.

UNEXPLAINED PULMONARY HYPERTENSION

Cases in which there are no demonstrable changes to account for the pulmonary hypertension are referred to as *primary pulmonary hypertension*. Until more information is forthcoming concerning the pathogenesis of these cases and the reflexes that influence pulmonary vascular tone, these should be referred to as cases of *unexplained* pulmonary hypertension. Reported cases of so-called primary pulmonary hypertension in which vascular occlusive lesions, arteritis, persistence of fetal-type arteries, abnormal communications between bronchial and pulmonary circulation, and ingrowth of intimal fibrous tissue into the pulmonary arteries from Sperrarterien should be classified as secondary pulmonary hypertension. When these are eliminated, very few authenticated cases remain. The few well-documented cases are more frequent in females, children, and young adults. This is in contrast to the secondary form of pulmonary hypertension seen in pulmonary disease. Considerable confusion in regard to primary pulmonary hypertension continues to exist because it is difficult to evaluate the primacy of certain vascular lesions. Experimentally, fibrin and even nitrogen bubble emboli in the pulmonary vessels may produce end-stage lesions that could be interpreted either as being secondary to hypertension or as being evidence of primary pulmonary arteriosclerosis. In the human being, healed thromboemboli may be indistinguishable from primary alterations in the vascular wall. On the one hand, arteritis may give rise to thrombi, and on the other thromboemboli may produce arteritis. A proper interpretation of the correct sequence in which these lesions develop is essential for the proper evaluation of the causes and classification of pulmonary hypertension.

tural changes in the blood vessels are entirely inadequate to account for the cor pulmonale. In the obesity syndrome, of course, there is no emphysema or any other notable primary structural alteration in the pulmonary vascular bed. Situations of this sort indicate that such factors as hypoxia, hypervolemia, etc., are perhaps the primary factors in the development of pulmonary hypertension rather than the structural alterations that develop later—in the destructive and irreversible phases of pulmonary disease processes. In *kyphoscoliosis* and in *unilateral thoracoplasty*, unilateral kinking of vessels is probably not a factor because the secondary vascular manifestations of pulmonary hypertension are equally reflected in both lungs.

In an entirely different area of lung disease, *the diffuse interstitial, inflammatory, and fibrotic processes*, cor pulmonale also occurs. In this group, which includes nonspecific interstitial fibrosis, berylliosis, sarcoid, certain forms of pneumoconiosis, etc., the blood vessels throughout the lung are encased in an environment of fibrous tissue, inflammatory exudate, granulomas, and edema. This reduces the distensibility of the vascular bed. The alveolar-capillary block and diminished ventilation of the lung in these conditions contribute important functional disturbances that favor the onset of pulmonary hypertension.

A general scheme of the pathogenesis of pulmonary hypertension in pulmonary disease is presented in the diagram, "Pathogenesis of Cor Pulmonale in Chronic Pulmonary Disease and Chest-cage Deformities" (page 13-7).

CHANGES IN THE VASCULAR BED

Direct structural involvement of the pulmonary arterial system by *thrombi*, *embolic carcinoma*, *polyarteritis*, or *schistosomiasis* obviously increases the resistance to the flow of blood. Plexiform vascular arrangements have been observed in these conditions, similar to those noted in pulmonary hypertension secondary to congenital cardiovascular disease. Whether these plexiform vascular arrangements are bypasses, vascularized granulation tissue, or shunts is not always entirely clear.

In cor pulmonale, the most consistent and prominent morphologic changes in the pulmonary vascular bed are actually secondary manifestations to the alterations in blood flow, volume, and tension produced by the various causes of chronic cor pulmonale. These changes consist basically of *atherosclerosis in the larger elastic arteries, hypertrophy (or at least apparent thickening) and the development of a longitudinal muscle layer of the muscular arteries, and fibrosis of the intima in the smaller arteries and precapillary arterioles*. The evaluation of muscular thickening is difficult because of the artifact produced by contraction.

Other changes consist of autochthonous *arterial thrombi* and *necrotizing arteritis or arteriolitis*. These thrombi may become so unrecognizable through organization as to be confused with arteriosclerosis (Fig. 13-1).

occupational factors to emphysema, bronchitis, and asthma However, since such a high proportion of cases of emphysema and bronchitis have their origin in industrial causes, a specific relationship with occupational hazards will probably be demonstrable in a high proportion of cases

The prevalence of cor pulmonale as a factor in the causation of disability will ultimately be proved higher than in many statistics, this becomes self-evident when one notes that autopsies are made in only a small proportion of individuals who died from occupation-related disease Death may also occur from some other cause while cor pulmonale may have been present as a component factor in disability Only serial and detailed examination of individuals routinely exposed to hazardous substances while employed would reveal the true prev
trial dise

There
is on the increase This may be partly explained by the fact that ultrahazardous occupational exposures have been eliminated in most civilized communities Formerly, such excessive exposures may have destroyed workmen before they had a chance to develop cor pulmonale. Now they survive and the repetitive injury to their pulmonary vasculature results in cor pulmonale. It has also been suggested that air pollution, which ultimately is of industrial origin, may be a material factor in the causation of bronchitis and cor pulmonale (Flint, 1954). This suggestion merits serious further exploration, for if it is true, persons other than workmen are involved. It is certainly true that in the so-called neighborhood cases of *berylliosis*, cor pulmonale has been a prominent cause of death, even among children

More cases of cor pulmonale will be detected in life if the rigid standard, requiring a right ventricular wall of at least 5 mm in thickness for a diagnosis of cor pulmonale, be reconsidered. In view of the fact that the thickness of the right ventricular wall can be materially influenced by the degree of distention of the chamber, the mural thickness cannot serve as a rigid criterion of cor pulmonale A simple calculation will suffice to illustrate that the state of contraction or distention of the right ventricle is an important determinant of the thickness of the ventricular wall. As the muscle mass remains constant, whether in a state of contraction or distention, it should be apparent

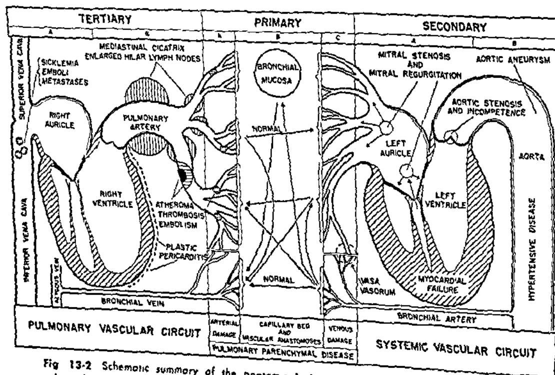

Fig 13-2 Schematic summary of the anatomic factors involved in the pathogenesis of cor pulmonale.

Occupational aspects of cor pulmonale

G. W. H. SCHEPERS

ETIOLOGY AND PREVALENCE

Occupational factors are responsible for a large proportion of all the cases of cor pulmonale which develop in adults In some countries, where children are employed in hazardous industries, cor pulmonale of occupational origin has occurred even in adolescents Statistics about the true incidence of industrial cor pulmonale are scanty During the 20 years from 1931 to 1950 the percentage of cases in which cor pulmonale was the cause of death in the pneumoconioses was variously reported as being from 14 8 per cent (Middleton, 1936) to 50.2 per cent (Gooding, 1946) These variable figures are partly due to the greater or lesser prevalence of tuberculosis and of various complications as causes of death This is because, under the heading of pneumoconiosis, greater or lesser numbers of cases of silicosis, anthracosis, or asbestosis were included It is well established that asbestosis yields a high proportion of deaths from cor pulmonale Silicosis in the advanced stages is terminated by cor pulmonale in inverse proportion to the prevalence of tuberculosis. In the majority of instances, cor pulmonale is, however, a terminal factor also in cases of tuberculosis complicating silicosis. Among anthracotic patients, the percentages of deaths due to cor pulmonale vary, apparently according to the free silica content of the coal dust and the relative prevalence of progressive massive fibrosis In anthracotic patients with tuberculosis (Wells, 1954b), cor pulmonale is a significant additional factor in the causation of death. On the contrary, the heart is seldom involved in persons with siderosis unless massive fibrosis has occurred. In the latter cases, the silicotic disease is more important than the siderotic process in the genesis of cor pulmonale, though some synergism apparently occurs. Cor pulmonale tends to be more prevalent among the siderosilicotic patients than among those with silicosis only.

In addition to the classical forms of pneumoconiosis, emphysema, bronchitis, asthma, and bronchiectasis may contribute a significant number of cases of cor pulmonale which have their ultimate origin in occupational factors Emphysema has gained increasing recognition not only as a pulmonary complication of the pneumoconioses, but also as a primary result of exposure to dusts and other injurious respiratory hazards (Mayer et al., 1956). Bronchitis and asthma may develop as occupation-related diseases (Schepers, 1955b), while bronchiectasis occurs much more rarely as a primary sequel to industrial exposures As emphysema, bronchitis, and asthma have increased in incidence, especially among those members of the community who are gainfully employed, it is of interest to note that cor pulmonale is cited as a complication in a comparatively high proportion of cases. Among 45 cases of emphysema studied, Griggs et al (1939) reported cor pulmonale in 29 per cent This is the lowest incidence cited, and the authors did not comment separately on bronchitis or asthma Cor pulmonale has been reported much more frequently in relation to emphysema, bronchitis, and asthma by other workers. The various statistics have not yet been analyzed to define the causal relationship of

tinal lymph nodes resulting from inhaled dusts, kinking and stenosis of the pulmonary artery by *chest deformities* due to industrial accidents, and showers of emboli arising from venous damage at remote points may similarly *lead to cor pulmonale*. Secondary cor pulmonale, of course, can be a sequel to disease of the systemic vascular circuit which results in cardiac failure and which may have its origin in occupational factors

Usually, occupational cor pulmonale occurs in a chronic form, and in most instances it arises insidiously. In some cases, however, the cardiac reaction to the pulmonary disease develops more rapidly and dramatically. This result is particularly likely in association with those lung states in which relatively acute impairment of the breathing surface is brought *about* (e.g., *chemical inflammatory* states, edema, vascular necrosis)

The various stages of cor pulmonale (Fig. 13-3) are all typical for occupational *cor pulmonale*. *Stage I* is usually *not* diagnosable unless special precautions are taken to elicit signs which are suggestive of it. This stage is usually also reversible, provided the causative lesion in the lungs is amenable to therapeutic or spontaneous amelioration. Stage II is associated with symptoms and is more readily recognizable as a clinical entity because of its characteristic radiographic appearances and electrocardiographic accompaniments *Stage III* is that which is usually encountered at autopsy when death has been due to the cor pulmonale. Figure 13-4 *represents a typical* example. Features of this case which merit special recognition are hypertrophy of the myocardium, of the trabeculae carneae, and of the papillary muscles of the right ventricle; moderate distention of the right ventricle; prominence of the pulmonary outflow tract, which is covered by fat; enlargement of the pulmonary artery, the internal diameter of which equals that of the aorta; marked distention of the right atrium with prominent muscular ridges; incompetence of the tricuspid valve. In the case shown in Fig. 13-4, in addition to the extensive destruction of the vascular bed, there was concomitant hypertrophy of the bronchial arterial system.

PATHOGENESIS

Anatomic mechanisms which *may induce* cor pulmonale *may be classified as shown in* Table 13-2.

The occupational factors which involve the *pulmonary arterial trunk* and main vessels are relatively few. *An aneurysm of the aorta* or the *sinus of Valsalva* which results from *occupational trauma* may subsequently compress the pulmonary trunk. Gross *thoracic deformities*, which may result from occupationally *derived sternal, vertebral*, or costal damage, may effectively impair the pulmonary circulation by compressing or kinking the *main trunk*. *The pulsatile excursions* of the main pulmonary vessels may also be impaired through external fixation by *incarcerating lymph nodes, as in silicosis* and tuberculosilicosis, or by *mediastinitis*, such as may be sequential to a bron-

that the mural thickness may vary through a range of plus or minus 100 per cent, according to whether the surface area of the ventricle is doubled or halved by distention or contraction.

PATHOLOGIC ANATOMY

In respect of its anatomic features, cor pulmonale does not differ materially in the industrial series from cor pulmonale of nonoccupational origin. Inasmuch as it usually occurs in the older age group, the occupation-related disease affects a heart which may simultaneously be the seat of degenerative changes resulting from hypertension, arteriosclerosis, coronary stenosis, etc. In these respects, cor pulmonale of occupational origin may differ from cor pulmonale sequential to congenital factors.

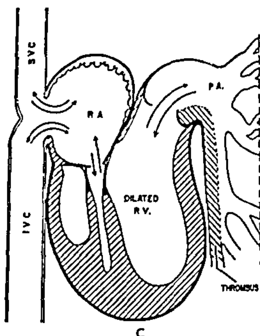

Fig. 13-3. Summary of the anatomic changes which occur in the progression of cor pulmonale from its subclinical to its clinical state.

It occurs not uncommonly that in the occupational variety, there is *hypertrophy of both the right and the left ventricle.* Whether both hypertrophic changes are ascribable to the occupational factor has not yet been demonstrated satisfactorily. In cor pulmonale accompanied by an increased cardiac output, there is a logical explanation for the associated hypertrophy of the left ventricle If simultaneously some unrelated systemic disease elevates the left ventricular pressure, hypertrophy of the left myocardium once more is explicable But neither systemic disease nor increased cardiac output may be present to account for the left ventricular enlargement. There is at least some experimental evidence to indicate that certain inhaled siliceous dusts of the submicron amorphous variety may elevate the systemic blood pressure at the same time that the pulmonary pressure rises in response to the parenchymal changes.

As an occupational disease, cor pulmonale usually occurs as the primary variety due to disease originating in and topographically restricted to the lungs (Fig. 13-2) Much less frequently, cor pulmonale may also be sequential to tertiary mechanisms promoted by occupational factors. Thus, cicatrizing medias-

paratively inert inhaled substances, such as coal dust, may bring about the same effect through the massive infiltration of the perivascular adventitia by koniophores (Fig. 13-5C). Obstruction of the vessel lumen may be thus produced without any appreciable collagen deposition However, fibrosis usually accompanies the process of cellular proliferation around the blood vessels (Fig 13-5D).

Changes which occur in the walls of blood vessels are usually less dramatic than the foregoing but may be equally disabling. As a result of sustained elevation of the pulmonary arterial pressure the muscular coat may hypertrophy considerably. It is difficult, however, to gage when this process has attained a pathologic degree, as the thickness of the muscular layer is largely influenced by the state of contraction or relaxation in which the pulmonary vessels were fixed at death In silicotic patients, however, there seems to be a predominant tendency for the blood vessels to be in a relatively spastic state. Arterial spasm of even a moderate degree may elevate the pulmonary tension considerably. The causal relationship between medial myohypertrophy and cor pulmonale is more directly apparent when such muscular hyperplasia occurs regionally (Fig 13-6A).

Degeneration of the muscle layer must inevitably affect its efficiency as a transit system for the perfusion of parts of the lung parenchyma supplied by it (Fig. 13-6B). While such fibrotic changes often occur in pneumoconiosis in the absence of any locally demonstrable causative agent, foreign

chial or esophageal erosion by silicotic lymph nodes, or which may result from thoracic trauma with mediastinal hemorrhages. *Pulmonary tumors* of occupational origin, such as those resulting from the inhalation of chromic, cobaltic, arsenical, nickel, and asbestos dusts, rapidly involve the mediastinal lymph nodes and thus precipitate cor pulmonale As a final event in long-standing elevated pulmonary tension, *thrombosis* is a factor in aggravating preexisting cor pulmonale or even in initiating this cardiac complication

By far the largest number of illustrations of specific industrial causes of cor pulmonale may be found among the lesions of the intrapulmonary blood vessels. The perivascular reactions are both the more conspicuous and the more important among these. During exposures to toxic or irritating substances, such as *chemical fumes and gases*, intrapulmonary inflammatory changes of variable severity and chronicity result The usually dispersed localization of these reactions results in widespread involvement of multiple intrapulmonary vessels This inflammatory state may by itself induce acute cor pulmonale, which not infrequently is the immediate cause of death in such individuals More usually the cardiac complication follows only after a prolonged interval, and the impairment of the pulmonary blood vessels is then caused by *perivascular fibrosis.* This may take the form of collagen hyperplasia (Fig 13-5A) or may result from proliferation of the elastic lamina (Fig 13-5B) Even com-

which are quite insufficient to sustain the circulation to the appropriate pulmonary sector (Fig 13-7C). The siliceous particles may often be demonstrated by polarized-light microscopy within these proliferated tissues *Endarteritis obliterans* of equally extraneous origin is particularly likely to occur in the lungs of employees in asbestos industries (Fig. 13-7D) At low-power magnification, the responsible mineral agent is frequently undetectable in the intimal zone, but coarser asbestos bodies may be found in the vascular adventitiae. Oil-immersion microscopy may then be resorted to, and the asbestos fibers will usually be demonstrable in the intima as well.

In vessels whose lumens have not been completely occluded by intimal proliferation, the process may be completed by *thrombosis* The occurrence of such clots and their subsequent dislodgement and reimpaction as *emboli* further along the blood vessel induce marked *vascular spasm*, which may be a material factor in precipitating a more advanced stage of cor pulmonale. Such episodes occur rather frequently in industrial personnel who are transferred from one inhalation hazard to another.

Bronchopulmonary vascular shunts are not specific for the occupationally determined cases of cor pulmonale. The pneumoconioses, and particularly asbestosis, tend, however, to foster their development.

bodies are not infrequently discovered within the vessel wall (Schepers, 1955a). They may be present there without apparently causing any pronounced local reaction (Fig 13-6C). On the other hand, the presence of isolated foreign agents, such as asbestos fibers, may induce a conspicuous response, which when widely dispersed in the vessels of the lung, undoubtedly may serve as an explanation for coexistent cor pulmonale.

Occlusion of the vascular lumens may occur on a widespread scale in the occupational pulmonary diseases, but may be frequently missed because the identity of the blood vessels is soon obliterated Vessels of all calibers may be simultaneously affected, or the brunt of the damage may fall selectively on smaller or on larger vessels The lesser arteries and venules are affected most severely in the occupational diseases in which highly active irritant substances constitute the specific hazard Thus the lungs of victims of metallic poisoning frequently display widely disseminated intimal proliferation in minute pulmonary vessels of a degree sufficient to create a significant impediment to the pulmonary circulation (Fig 13-7A). In these occupational diseases, however, intimal proliferation may affect even relatively large blood vessels In such cases, the explanation not infrequently seems to lie in the associated distortion and narrowing of the blood vessel through external cicatricial forces (Fig. 13-7B). In addition to the cellular phases of the intimal proliferation, inhaled foreign substances, such as quartz dust, cristobalite, or tridymite, provoke collagen formation The lumen of the vessel eventually becomes reduced to one or more minute canals,

lung lobe in which all blood vessels have been occluded. The capacity of several of these lesions to induce cor pulmonale is self-evident. In *progressive massive fibrosis* of coal workers, this cardiac complication is particularly prevalent.

In addition to distortion, compression, or obliteration of blood vessels in such areas of massive fibrosis, there is the added factor of loss of capillary bed. In these cruder examples, there is loss both of aeration and of perfusion. Cor pulmonale may, however, occur through impaired respiratory activity at the capillary level with or without decreased aeration. In those pneumoconiotic conditions, such as talcosis, in which the bronchi sustain the brunt of the damage so that their lumens become occluded, the role of impaired aeration as a factor in eliminating the function of the capillaries is self-evident (Fig. 13-9B). More usually the main damage occurs at the bronchiolar level, and there usually is an associated *bronchiolar spasm*. The latter probably is a material factor in the genesis of some forms of emphysema which occur in industrial workers and which later become associated with cor pulmonale.

One essential change induced by *emphysema* is impaired aeration. In view of the tremendous reserve of the lungs, the emphysema would have to be of a very advanced grade before cor pulmonale could follow merely as a result of reduced aeration of mural capillaries. In emphysema of occupational origin,

ous pneumoconioses The relationship between the cor pulmonale and the occupational exposures may then be the more readily demonstrated. In the pneumoconioses resulting from inhaled metallic substances, the unit lesions are more often than not perivascular in distribution and effectively embarrass the pulmonary circulation because of their prevalence (Fig. 13-8A). Even in areas of diffuse or massive granulomatous reaction in which some vascular proliferation occurs, the newly formed capillaries soon acquire a collagen sheath which effectively eliminates such channels as agents for the maintenance of the respiratory function (Fig. 13-8B) The relationship of the silicotic nodule to the pulmonary blood vessels is usually not easily recognized once hyalinization has been completed Elastic tissue staining may, however, demonstrate the skeletons of such blood vessels even in mature nodules (Schepers, 1955a). In the earlier phases of silicosis, and particularly in siderosilicosis, it is frequently possible to demonstrate the perivascular distribution of the nascent nodule (Fig 13-8C). Even in asbestosis, there may be relatively large focal collections of fibrous tissue around distorted and stenosed blood vessels (Fig 13-8D).

Vascular destruction or obliteration occurs on a much grander scale in tuberculosilicotic fibrosis, carnification of unresolved pneumonic or atelectatic pulmonary segments or lung lobes, or when neoplasia complicates a pneumoconiotic process A fibrotic mass, which measures 5 to 7 cm in maximal diameter (Fig 13-9A), may represent a completely devitalized

Focal fibrosis in asbestosis involving a medium-sized blood vessel which is distorted and stenosed. Mallory, ×65.

stitial pulmonary fibrosis, therefore, necessarily terminates in cor pulmonale.

In addition to the devascularizing processes, various occupational diseases of the lungs, but especially asbestosis, promote the excessive proliferation of capillary plexuses and the development of short-circuiting vascular shunts Such changes add further to the embarrassment of the circulation, much of the blood circulating through the affected areas failing to become oxygenated

Numerous other subtle mechanisms operate at the alveolar plane While some mechanisms would lead to cor pulmonale by direct obstruction to blood flow, others achieve their effect on physiologic principles. *Hypoxia* (see *diagram below*) not only exerts its action on the chemoreceptors of the lung, but also influences the brain stem, pulmonary blood vessels, bronchioles, bone marrow, and myocardium. The resultant hypervolemia and increased cardiac output are therefore responsible for the pulmonary hypertension, cardiac hypertrophy, dilatation, and ultimate failure It is doubtful, however, whether cor pulmonale ever occurs as an occupation-related disease purely on such a physiologic basis There usually is such abundant concomitant pulmonary disease that the role of obstructive factors cannot be negated. *As a clinical disease, the cor pulmonale associated with the pneumoconioses tends to be predominantly of the low-output type,* though it should be conceded that the high-output variety occurs with sufficient frequency in industrial workers to support the suggestion that, in some cases, functional factors may be of paramount significance in the genesis of the disease

cor pulmonale ensues the more readily because there frequently is associated focal atelectasis, while there may be obliteration of other alveoli by processes of impaction of koniophores in the alveoli. The emphysema no doubt also subjects the capillaries to tension and thus impedes the circulation through them. The emphysema is frequently associated with mural thickening and fibrosis, which additionally occlude alveolar capillaries (Fig. 13-9C).

An obstructing membrane interposed between normally perfused alveolar capillaries and normally aerated alveoli would frustrate the respiratory function and thereby induce cor pulmonale. Such a membrane may be of extraneous origin but may also be the result of proliferation of the mural epithelium. The latter occurs relatively frequently in persons exposed to *beryllium* (Fig. 13-9D). Through infiltration of the alveolar walls by cells or collagen (Fig. 13-10A and B), the capillary plexuses may be eliminated. The devascularization process may be completed by thrombosis. These changes are particularly common in Shaver's disease, diatomaceous earth pneumoconiosis, and in exposures to tridymite and cristobalite.

Even in the presence of advanced interstitial fibrosis, capillaries may yet survive over the surfaces of the newly deposited stromal elements. This is the more likely when the reticulum or excessive elastic tissue rather than collagen (Fig. 13-10C and D) constitutes the skeletal framework. Not every case of inter-

and still containing cartilage, the nature of the bronchial *Sperrarterie* becomes even more evident The "longitudinal" muscle fibers show considerable development These longitudinal fibers, if thoroughly investigated, reveal a spiraling course in the vessel wall, and project into the lumen Such anatomic arrangement may be considered to be the cause of the contraction of the blood vessel (Fig 13-11B)

Such anastomoses were still encountered at a level of bronchi of 1.2 to 1 3 mm in diameter (Fig. 13-12) The outer diameter of the anastomosis is around 100 μ It should be noticed that the branches of the pulmonary artery which anastomose with the bronchial *Sperrarterie* are not of the muscular but of the elastic type The author's studies with the vinyl cast showed such anastomoses to exist in the vascular system of the mediastinal pleura

Abundant sensory nerves and ganglion cells were found in the bronchial *Sperrarterie* by the silver-impregnation method. Such anatomic structure may be compared with that found in the glomus at the periphery of the extremities In the lung, this structure plays an important role in the control of the pulmonary blood pressure (Fig 13-13).

The pressure relationship between the bronchial and pulmonary arterial systems, as well as the flow in the anastomoses between both,

f dilata-

As the blood pressure in the bronchial artery is several times higher than that in the pulmonary artery, the blood flow at the anastomosis will take the direction which is shown in Fig 13-14B In normal lungs, however, the blood volume of the bronchial artery is minimal in comparison with the total pulmonary blood flow As a volume factor, its influence upon respiratory function may be disregarded. It is doubtful whether such minimal volume of bronchial blood flow would contribute to the nutrition of the alveolar wall via the anastomosis or not According to the pressure difference of both arteries, the peripheral resistance of the pulmonary artery will increase at the periphery Accordingly, the blood flow of the pulmonary artery in this area is somewhat decreased Liebow et al (1950) suggested that in an affected lung, the increased bronchial arterial flow draining into the pulmonary artery via the developed anastomoses would prevent the pulmonary blood flow to the affected area and

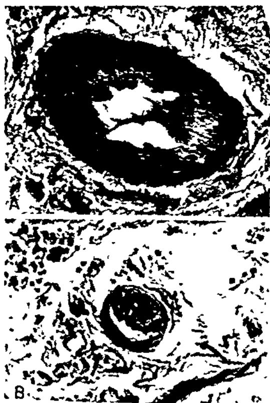

Fig. 13-11. A So-called *bronchial Sperrarterie. It is apparent that the wall is composed of inner longitudinal and outer circular muscle fibers. would prevent venous admixture This mechanism, however, is difficult to imagine under normal conditions, where the *Sperrarterien* are occluded and no blood flows through the anastomoses If, however, the difference in blood pressure of the two arteries changes considerably, the collaterals will open.

The anastomoses between the pulmonary and the bronchial arteries in the normal lung have been widely discussed by many investigators in the past Reports by Miller (1950), who denies the existence of such anastomoses, are mainly based on experimental data *in dogs* The author's own observations in dogs showed no bronchial *Sperrarterien* in this species, and no anastomoses between the two arterial systems could be demonstrated. Presumably, the

3

The role of bronchial circulation in chronic pulmonary diseases

TAKASHI NAKAMURA

It has been pointed out that in chronic pulmonary diseases, the increased development of bronchial blood vessels or the development of precapillary anastomoses between bronchial arteries and branches of the pulmonary artery plays an important role in the circulation. It has been felt that when cardiopulmonary dynamics is studied in these diseases, the role of the bronchial circulation cannot be disregarded.

For several years, the author and his coworkers have studied the morphology and physiology of the bronchial vascular system; they have succeeded in measuring the bronchial flow.

OUTLINE OF BRONCHOPULMONARY CIRCULATION; *SPERRARTERIE*

As already known, the *bronchial arteries* originate from the aorta or intercostal arteries, enter each lung along the main bronchus, supply blood to the bronchial wall and the adjacent structures along the bronchial tree, and finally terminate at the periphery of the bronchial tree. During its course, the *peribronchial capillary bed* is formed. The capillary blood becomes venous and drains into the pulmonary vein. Only the blood of the bronchial artery providing the hilar region will return to the azygos and hemiazygos veins via the extrapulmonary bronchial vein (or pleurohilar vein). *The venous blood draining from the peribronchial capillary bed mixes with arterial blood* of the pulmonary capillaries, reaches the pulmonary vein, and finally returns to the left atrium. This represents *a postcapillary anastomosis* between the bronchial and pulmonary venous circulations. There are, in addition, important anastomoses between the bronchial and the pulmonary arteries at the precapillary level.

At present, there are two concepts of the anastomoses between the bronchial artery and pulmonary artery. The German school maintains that there are anastomoses between these systems of arteries, while the American and English schools deny them. In order to clarify this controversy, serial sections on several normal adult lungs were made to study the blood vessels along the bronchial tree. *This revealed that clear arterial anastomoses exist between them.* When a normal bronchial artery was followed from the hilar region to the periphery of the lung, a layer of longitudinal muscle fiber directly below its endothelium appeared in the peripheral branches. These longitudinal muscle fibers are rarely found in the branches of the bronchial arteries along large bronchi, if found, they appear as a single layer of muscle cells sometimes protruding as a crescent into the lumen. Such longitudinal muscle fibers become more prominent around middle-sized and smaller bronchi with an internal diameter of less than 3 mm. The walls of bronchial arteries in this area consist of circular muscle fibers in the media and longitudinal muscle fibers in the subintima (Fig. 13-11). This ramification was called *bronchial Sperrarterie* by Hayek.[1] In the walls of smaller bronchi with a caliber of less than 1.5 mm

[1] The nearest English translation is "bronchial blocking artery" or "bronchial barrier artery."

ured by Bruner and Schmidt, who used the bubble flowmeter technique Using the same principle, similar results have been reported by the author, who has also designed a new method for the measurement of the bronchial blood flow in human lungs

In chronic lung disease, the anastomoses between the bronchial and the pulmonary arteries become more extensive, in other words, the anastomoses between the two arterial systems are in a functional status. Then, bronchial arterial flow drains into the pulmonary arterioles under a high pressure, which is only slightly lower than that of the aorta Consequently, the blood flow in the pulmonary capillaries is greater than that which reaches the pulmonary artery from the right heart. If the capillary blood flow of the pulmonary alveoli and right cardiac output are separately measured, the bronchial blood flow can be obtained by their difference

Some of the blood from the right heart will, however, return to the left atrium without coming in contact with the alveolar air, because of the existence of arteriovenous capillaries This represents *a true venous mixture* and might be termed an "anatomic venous mixture" In chronic pulmonary diseases, this process is remarkably increased (Wilson et al, 1951) As such venous shunt carries the blood which leaves the lung without coming in con-

connections between the pulmonary system and the bronchial system of dogs occur at the capillary level.

Vinyl cast studies of diseased *human lungs* clearly demonstrate the presence of precapillary anastomoses through *Sperrarterien*, and anastomoses through dilated capillary vessels appearing like arterial anastomoses *In other words, in human lungs, both anastomoses between the system of the bronchial artery and that of the pulmonary artery, and capillary anastomoses exist, while in dog lungs, only the latter are found*

Aside from these intimate collateral relationships of the bronchial and pulmonary circulation within the parenchyma of the lung, there exists a communication at the pulmonary hilum. It is an anastomosis between the extrabronchial veins (pleurohilar veins) and pulmonary veins. The pulmonary veins communicate with the systemic venous system by way of this passage. Its significance has already been pointed out by the author, by Gilroy et al., and by Hurwitz et al.

BRONCHIAL BLOOD FLOW

Method of Measurement. The bronchial arterial blood flow in the dog has been successfully meas-

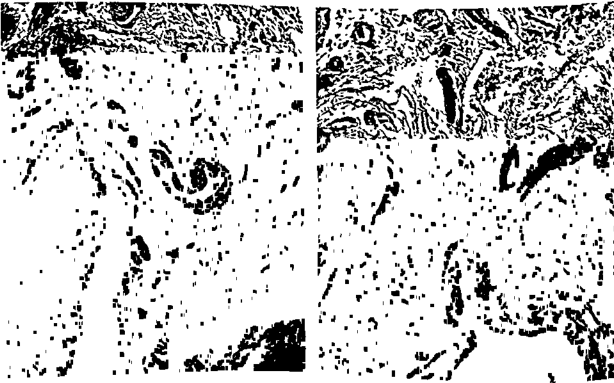

Fig. 13-12. A and B. A small branch of the bronchial artery (*bronchial Sperrarterie*), along the smallest bronchus with cartilage, sends a thin-walled branch towards the submucosal layer Normal lung. was found impossible to perform alveolar air sampling in patients with severe obstruction of the air passages (pulmonary emphysema, etc.), because of variability in the determination of alveolar air.

The maximum error in determination of the cardiac output by the Fick's method should not be above 5 per cent, if the error in measurement of O_2 in the arterial and mixed venous bloods is only 0.1 vol per cent, when arteriovenous O_2 difference is 4 vol per cent. In the measurement of pulmonary capillary blood flow, on the other hand, an error of 0.5 mm Hg of alveolar CO_2 pressure corresponds to about 10 per cent of blood flow. Therefore, in the determination of the value of the bronchial blood flow, the above analytic error should be taken into consideration. After considering these points, however, it may still be concluded that in several patients with chronic pulmonary diseases, a large quantity of bronchial blood flows into the lungs.

New Way of Measuring Bronchial Blood Flow by the Dye-dilution Method. At present, the dye-dilution method is employed in the author's laboratory for the measurement of bronchial blood flow. The method consists of a simultaneous measurement of left and right ventricular outputs with two cardiac catheters.

One catheter is introduced into an antecubital vein and advanced until the tip lies in the main pulmonary artery. Another catheter is advanced through a second vein until its tip lies in the superior vena cava. A Cournand needle is inserted into the bronchial artery. Three to four cubic centimeters of Evans blue or Bromsulphalein is rapidly injected into the superior vena cava. Simultaneously, blood is sampled in small test tubes from the pulmonary artery and brachial artery every 1 to 2 sec. In sampling from the pulmonary artery, the end of the catheter is inserted into a negative pressure chamber, with a pressure of about 200 mm Hg below atmospheric, and the small test tubes in the chamber are automatically rotated. Dye concentration in serum is measured by means of an electrophotometer, and two dye-dilution curves are inscribed.

The curves drawn from the brachial artery and pulmonary artery should measure the outputs of the left and right ventricles, respectively. Then, the difference between the two should be attributed to an increase of the bronchial blood flow.

Experiments were attempted at first in normal dogs, and the outputs of the left and right ventricles were found to be practically identical (Table 13-3). Then a shunt was made between the left subclavian and the left pulmonary artery in other dogs, and the outputs were measured by the dye-dilution method. At the same time, blood flow through the shunt was directly measured by means of a bubble flowmeter placed in the course of the shunt and by bleeding from the anastomotic

tact with alveolar air, it will not be included in the pulmonary capillary blood flow measured here. Therefore, if the value obtained by taking the anatomic venous mixture from the right cardiac output is subtracted from the value of the pulmonary capillary blood flow, a more correct blood flow of the bronchial circulation will be given. The anatomic venous mixture ratio can be calculated as a ratio of the left cardiac output, which is the total sum of right cardiac output plus bronchial blood flow. Its blood flow should also be calculated in relationship to the left cardiac output.

The blood flow of the bronchial artery can be obtained by the following equation.

$$BF = PCF - \left[CO - \frac{(CO\ BF)X}{100}\right]$$

$$BF = \frac{PCF}{1 - \frac{X}{100}} - CO$$

where BF = bronchial blood flow
CO = right cardiac output
PCF = pulmonary capillary blood flow
X = anatomic venous mixture ratio

The expression "bronchial blood flow" indicates that part of the arterial blood flow of the bronchial artery which mixes with blood of the pulmonary arterioles through precapillary anastomoses.

A Method to Measure Pulmonary Capillary Blood Flow. The method developed by Bing et al (1947) was adopted. Capillary blood CO_2 concentrations upon entering and leaving the alveoli may be determined by the equilibration method of CO_2 in the alveoli. Pulmonary capillary blood flow can be calculated by Fick's principle

$$\begin{Bmatrix}\text{Pulmonary}\\ \text{capillary}\\ \text{blood flow}\end{Bmatrix} = \frac{CO_2 \text{ output (ml/min)}}{\begin{bmatrix}\text{concentration of blood } CO_2\\ \text{entering the alveoli (vol \%)}\\ -\text{ concentration of blood } CO_2\\ \text{leaving the alveoli (vol \%)}\end{bmatrix}}$$

In order to calculate the concentration of CO_2 of the capillary blood which leaves the alveoli, CO_2 in the alveoli is measured by the end-inspiratory method of Haldane and Priestley. In order to calculate the concentration of CO_2 of the capillary blood which enters the alveoli, three kinds of mixed gas consisting of 4, 5, and 6 per cent of CO_2 to O_2, respectively, are deeply inhaled after full expiration. The succeeding breath is then held for 8 to 10 sec in order to obtain an equilibrium between the capillary blood and alveolar gas. The patient is finally instructed to exhale forcefully. The CO_2 in the alveoli is then measured. If three values of alveolar CO_2, after inhalation of three CO_2 mixtures, agree within 0.2 per cent, respectively, the blood which enters the alveoli and the alveolar air are considered to be well equilibrated. The average is taken. These two kinds of alveolar CO_2 tensions, corresponding to alveolar gas equilibrated with blood which enters and leaves the alveoli, are converted to concentration of blood CO_2 by *Singer's nomogram*, using arterial and venous oxygen saturation, pH, and hematocrit.

Method to Measure Anatomic Venous Admixture (Katori). Anatomic venous mixture can be measured by nullifying the venous mixture which is caused by poorly ventilated alveoli following inhalation of pure O_2 gas for over 20 min to replace N_2 in the alveoli. Venous mixture which still exists after inhalation of pure O_2 for a long time is the blood flow in the nonventilated alveoli. In other words, it is the real venous shunt.

After the subject has breathed pure oxygen during cardiac catheterization, arterial blood is sampled from the indwelling needle in the brachial artery and is immediately centrifuged anaerobically under low temperature. The plasma O_2 tension is measured polarographically by a mercury electrode. Oxygen tension in the alveoli is measured by the *Haldane-Priestley method*. The arteriovenous O_2 difference is determined from the blood gas analysis by the *Van Slyke manometric method*. The following equation may be obtained

$$\begin{Bmatrix}\text{Anatomic venous}\\ \text{mixture ratio}\end{Bmatrix} = 100 - \left(\frac{Y}{Y - G} \times 100\right)$$

where Y = arteriovenous O_2 difference (vol %)
G = (alveolar PO_2 − arterial PO_2) × B
B = O_2 volume dissolved in blood under 1 mm Hg O_2 tension at 37.0°C (vol %)

CRITICISM OF THE METHOD. At present, it is undoubtedly difficult to determine accurately the bronchial blood flow in man without surgery. The above method involves a few difficulties: (1) impossibility of a simultaneous measurement of pulmonary capillary blood flow and cardiac output in a steady condition, and (2) necessity of operator's skill and subject's cooperation for the CO_2 equilibration in the alveoli and for alveolar air sampling. In the author's experiments, all measurements were always performed under the same basal conditions, evaluated through O_2 consumption and respiratory quotient, in order to maintain the patient's state as steady as possible. The determination of alveolar air, after prolonged training of the subject, was repeatedly carried out in order to obtain constant values. Consequently, it

was found impossible to perform alveolar air sampling in patients with severe obstruction of the air passages (pulmonary emphysema, etc.), because of variability in the determination of alveolar air.

The maximum error in determination of the cardiac output by the Fick's method should not be above 5 per cent, if the error in measurement of O_2 in the arterial and mixed venous bloods is only 0.1 vol per cent, when arteriovenous O_2 difference is 4 vol per cent. In the measurement of pulmonary capillary blood flow, on the other hand, an error of 0.5 mm Hg of alveolar CO_2 pressure corresponds to about 10 per cent of blood flow. Therefore, in the determination of the value of the bronchial blood flow, the above analytic error should be taken into consideration. After considering these points, however, it may still be concluded that in several patients with chronic pulmonary diseases, a large quantity of bronchial blood flows into the lungs.

New Way of Measuring Bronchial Blood Flow by the Dye-dilution Method. At present, the dye-dilution method is employed in the author's laboratory for the measurement of bronchial blood flow. The method consists of a simultaneous measurement of left and right ventricular outputs with two cardiac catheters.

One catheter is introduced into an antecubital vein and advanced until the tip lies in *the main pulmonary artery*. Another catheter is advanced through a second vein until its tip lies in *the superior vena cava*. A Cournand needle is inserted into the brachial artery. Three to four cubic centimeters of Evans blue or Bromsulphalein is rapidly injected into the superior vena cava. Simultaneously, blood is sampled in small test tubes from the pulmonary artery and brachial artery every 1 to 2 sec. In sampling from the pulmonary artery the end of the catheter is inserted into a negative pressure chamber, with a pressure of about 200 mm Hg below atmospheric, and the small test tubes in the chamber are automatically rotated. Dye concentration in serum is measured by means of an electrophotometer, and two dye-dilution curves are inscribed.

The curves drawn from the brachial artery and pulmonary artery should measure the outputs of the left and right ventricles, respectively. Then, the difference between the two should be attributed to an increase of the bronchial blood flow.

Experiments were attempted at first in normal dogs, and the outputs of the left and right ventricles were found to be practically identical (Table 13-3). Then a shunt was made between the left subclavian and the left pulmonary artery in other dogs, and the outputs were measured by the dye-dilution method. At the same time, blood flow through the shunt was directly measured by means of a bubble flowmeter placed in the course of the shunt and by bleeding from the anastomotic

tact with alveolar air, it will not be included in the pulmonary capillary blood flow measured here. Therefore, if the value obtained by taking the anatomic venous mixture from the right cardiac output is subtracted from the value of the pulmonary capillary blood flow, a more correct blood flow of the bronchial circulation will be given The anatomic venous mixture ratio can be calculated as a ratio of the left cardiac output, which is the total sum of right cardiac output plus bronchial blood flow. Its blood flow should also be calculated in relationship to the left cardiac output.

The blood flow of the bronchial artery can be obtained by the following equation:

$$BF = PCF - \left[CO - \frac{(CO\ BF)X}{100} \right]$$

$$BF = \frac{PCF}{1 - \frac{X}{100}} - CO$$

where BF = bronchial blood flow
CO = right cardiac output
PCF = pulmonary capillary blood flow
X = anatomic venous mixture ratio

The expression "bronchial blood flow" indicates that part of the arterial blood flow of the bronchial artery which mixes with blood of the pulmonary arterioles through precapillary anastomoses.

A Method to Measure Pulmonary Capillary Blood Flow. The method developed by Bing et al (1947) was adopted. Capillary blood CO_2 concentrations upon entering and leaving the alveoli may be

CO_2 in

can be

$$\left\{ \begin{array}{l} \text{Pulmonary} \\ \text{capillary} \\ \text{blood flow} \end{array} \right\} = \frac{CO_2 \text{ output (ml/min)}}{\left[\begin{array}{l} \text{concentration of blood } CO_2 \\ \text{entering the alveoli (vol \%)} \\ -\text{ concentration of blood } CO_2 \\ \text{leaving the alveoli (vol \%)} \end{array} \right]}$$

In order to calculate the concentration of CO_2 of the capillary blood which leaves the alveoli, CO_2 in the alveoli is measured by the end-inspiratory method of Haldane and Priestley. In order to calculate the concentration of CO_2 of the capillary blood which enters the alveoli, three kinds of mixed gas consisting of 4, 5, and 6 per cent of CO_2 to O_2, respectively, are deeply inhaled after full expiration The succeeding breath is then held for 8 to 10 sec in order to obtain an equilibrium between the capillary blood and alveolar gas. The patient is finally instructed to exhale forcefully. The CO_2 in the alveoli is then measured. If three values of alveolar CO_2, after inhalation of three CO_2 mixtures, agree within 0.2 per cent, respectively, the blood which enters the alveoli and the alveolar air are considered to be well equilibrated. The average is taken These two kinds of alveolar CO_2 tensions, corresponding to alveolar gas equilibrated with blood which enters and leaves the alveoli, are converted to concentration of blood CO_2 by *Singer's nomogram*, using arterial and venous oxygen saturation, pH, and hematocrit.

Method to Measure Anatomic Venous Admixture (Katori). Anatomic venous mixture can be measured by nullifying the venous mixture which is caused by poorly ventilated alveoli following inhalation of pure O_2 gas for over 20 min to replace N_2 in the alveoli. Venous mixture which still exists after inhalation of pure O_2 for a long time is the blood flow in the nonventilated alveoli In other words, it is the real venous shunt.

After the subject has breathed pure oxygen during cardiac catheterization, arterial blood is sampled from the indwelling needle in the brachial artery and is immediately centrifuged anaerobically under low temperature. The plasma O_2 tension is measured polarographically by a mercury electrode Oxygen tension in the alveoli is measured by the *Haldane-Priestley method*. The arteriovenous O_2 difference is determined from the blood gas analysis by the *Van Slyke manometric method*. The following equation may be obtained

$$\left\{ \begin{array}{l} \text{Anatomic venous} \\ \text{mixture ratio} \end{array} \right\} = 100 - \left(\frac{Y}{Y - G} \times 100 \right)$$

where Y = arteriovenous O_2 difference (vol %)
G = (alveolar PO_2 − arterial PO_2) × B
B = O_2 volume dissolved in blood under 1 mm Hg O_2 tension at 37.0°C (vol %)

CRITICISM OF THE METHOD At present, it is undoubtedly difficult to determine accurately the bronchial blood flow in man without surgery The above method involves a few difficulties (1) impossibility of a simultaneous measurement of pulmonary capillary blood flow and cardiac output in a steady condition, and (2) necessity of operator's skill and subject's cooperation for the CO_2 equilibration in the alveoli and for alveolar air sampling In the author's experiments, all measurements were always performed under the same basal conditions, evaluated through O_2 consumption and respiratory quotient, in order to maintain the patient's state as steady as possible The determination of alveolar air, after prolonged training of the subject, was repeatedly carried out in order to obtain constant values. Consequently, it

was found impossible to perform alveolar air sampling in patients with severe obstruction of the air passages (pulmonary emphysema, etc.), because of variability in the determination of alveolar air

The maximum error in determination of the cardiac output by the Fick's method should not be above 5 per cent, if the error in measurement of O_2 in the arterial and mixed venous bloods is only 0.1 vol per cent, when arteriovenous O_2 difference is 4 vol per cent. In the measurement of pulmonary capillary blood flow, on the other hand, an error of 0.5 mm Hg of alveolar CO_2 pressure corresponds to about 10 per cent of blood flow. Therefore, in the determination of the value of the bronchial blood flow, the above analytic error should be taken into consideration. After considering these points, however, it may still be concluded that in several patients with chronic pulmonary diseases, a large quantity of bronchial blood flows into the lungs

New Way of Measuring Bronchial Blood Flow by the Dye-dilution Method. At present, the dye-dilution method is employed in the author's laboratory for the measurement of bronchial blood flow. The method consists of a simultaneous measurement of left and right ventricular outputs with two cardiac catheters.

One catheter is introduced into an antecubital vein and advanced until the tip lies *in the main pulmonary artery*. Three to four cubic centimeters of Evans blue or Bromsulphalein is rapidly injected into the superior vena cava. Simultaneously, blood is sampled *in small test tubes from* the pulmonary artery and brachial artery *every 1 to 2 sec*. In sampling from the pulmonary artery, the end of the catheter is inserted into a negative pressure chamber, with a pressure of about 200 mm Hg below atmospheric, and the small test tubes in the chamber are automatically rotated. Dye concentration in serum is measured by means of an electrophotometer, and two dye-dilution curves are inscribed

The curves drawn from the brachial artery and pulmonary artery should measure the outputs of the left and right ventricles, respectively. Then, the difference between the two should be attributed to an increase of the bronchial blood flow

Experiments were attempted at first in normal dogs, and the outputs of the left and right ventricles were found to be practically identical (Table 13-3). Then a shunt was made between the left subclavian and the left pulmonary artery in other dogs, and the outputs were measured by the dye-dilution method. At the same time, blood flow through the shunt was directly measured by means of a bubble flowmeter placed in the course of the shunt and by bleeding from the anastomotic

channel Table 13-4 shows that the difference between the two outputs corresponded roughly to the values obtained by the flowmeter and bleeding method Examination of these results led to the conclusion that the method was sufficiently accurate for measuring the shunted blood flow.

The difference between the outputs of left and right ventricles in healthy persons corresponded within 10 per cent of the right cardiac output in all (Table 13-5). However, in patients with tuberculosilicosis, bronchiectasis, pulmonary tuberculosis, or cancer of the lung, it was frequently observed that the difference was much greater (Table 13-6). It reached 53 per cent of the right cardiac output in a patient suffering from silicosis with massive density, while no such difference was noted in simple silicosis or in early stages of this condition plus minimal tuberculosis These figures agree fairly well with the results obtained by previously mentioned methods.

BRONCHIAL BLOOD FLOW IN HEALTHY PERSONS

According to the determinations of blood-flow studies in three healthy persons, pulmonary capillary blood flow presented a value close to cardiac output (Table 13-7). Bronchial blood flow was calculated to be 0 01 to 0 36 liters/min Considering the errors which must accompany this measurement, this is unquestionably insignificant The above results obtained from healthy persons are important for comparison with results obtained in diseased lungs

BRONCHIAL VASCULAR SYSTEM AND BLOOD FLOW IN CHRONIC PULMONARY DISEASES

In certain *chronic pulmonary diseases*, the increase in bronchial circulation has been well established by Liebow (1949, 1950) and others. The author's morphologic studies proved indirectly a similar phenomenon. In these conditions, when the bronchial blood flow was measured physiologically, an abnormally large figure was frequently obtained In cases with *destruction of pulmonary artery branches in diseased areas* (pulmonary tuberculosis, bronchiectasis, pulmonary silicosis), the bronchial artery was found to be remarkably developed Its dilated, twisting branches could be observed by the naked eye (Fig

Fig 13-15. A Marked twining and dilatations of the bronchial artery at the hilar region. Adult lung affected by tuberculosis (vinyl plastic cast) A p, pulmonary artery; A. br., bronchial artery B. Enormous plexiform branches of the bronchial artery form a fine mesh and wrap the tuberculous cavity from the hilus side, while nearly all the branches of the pulmonary artery are damaged around the cavity. Br, bronchus, A br, bronchial artery; P., enormous plexiform branches of bronchial artery; C, cavity. C. Bronchial arteries wind with marked development, while the pulmonary arteries are destroyed on the dilated bronchi and removed. Idiopathic bronchiectasis. Vinyl plastic cast Br, bronchus, A p, pulmonary artery; A br, bronchial artery.

A., anastomosis; A p., pulmonary artery; A.br., bronchial artery. B Dilatation and development of the bronchial arteries in the vicinity of conglomerated nodules. Marked inflammatory changes are present on the bronchial wall. Silicotic lung

13-15). Moreover, in the neighborhood of the affected areas, the anastomoses between the bronchial and pulmonary arteries are developed in a high degree (Fig 13-16) It may be noticed that *the bronchial artery is so dilated that it reaches the caliber of the pulmonary artery with which it anastomoses.* When such lungs are irrigated by saline solution through the bronchial artery at the autopsy table, the solution will flow out easier from the pulmonary artery than from the pulmonary vein, which is the normal passage (Fig. 13-16B)

The values of bronchial blood flow in six cases of *bronchiectasis* are presented in Table 13-8. When these results are compared with those of healthy persons or with data of cardiac output, attention should be paid to very high figures (last column).

The data obtained in cases of *silicosis* showed the same trend (Table 13-9). Ten of 13 examined cases, however, also had *tuberculosis,* which may contribute to the increase of bronchial blood flow. Wood and Miller, and Wells, described the overdevelopment of the bronchial arteries in silicosis According to the author's histologic studies in cases with simple *silicosis,* the dilatation and overdevelopment of the bronchial artery cannot always be demonstrated around pure silicotic nodules If, however, *bronchitis* or *any other inflammatory condition* is associated with the process, overvascularization is usually encountered (Fig. 13-16B).

Of three cases of uncomplicated silicosis which the author studied, the bronchial blood flow in two showed an increase to 0 26 and 0.61 liters/min, respectively, whereas, in the other case, a remarkable increase up to 3 55 liters/min was obtained Such an increased flow may be due to the afore-mentioned reasons

* Simple silicosis

† Unmeasured value. Averaged value in 8 cases of silicosis.

It is surprising that the bronchial blood flow increases to such an extent in these diseases.[a] According to the author's method, the measured value represents only the blood flow which reaches the pulmonary capillaries by way of the anastomosis between arterial systems This does not include the bronchial blood flow which returns immediately into the pulmonary veins Systemic blood flow from the intercostal arteries via pleural adhesions is also presumed to be of a large order

COR PULMONALE SECONDARY TO CHRONIC LUNG DISEASES

The incidence of cor pulmonale in chronic lung diseases has been reported by many investigators Using the criteria of Scott et al and Griggs et al, the author measured the walls of the left and right ventricle in 99 persons with healthy or diseased lungs (Table 13-10). The results were similar to those of others. Right ventricular hypertrophy (wall of right ventricle over 5 mm) was found in persons with pulmonary emphysema, silicosis, bronchiectasis, and pulmonary tuberculosis. *In most of these persons, the left ventricle was also found to be hypertrophied.*

In cor pulmonale, left ventricular hypertrophy has been reported by others Spain and Handler examined cases without systemic hypertension, aortic valvular diseases, or coronary arterial changes, and *found left ventricular hypertrophy in 90 per cent of the cases* The author's studies proved that the wall of the left ventricle measured over 12 mm in 61 per cent of the cases Even though several mechanisms (systemic hypertension, hypoxia, increase of cardiac output, anatomic connection between the muscle fibers of the left and right ventricles, and myocardial damage) were suggested, the explanations are mostly not satisfactory.

Cor pulmonale is a common occurrence in bronchiectasis, silicosis, and pulmonary tuberculosis. In the same conditions the bronchial arterial system is remarkably overdeveloped and the bronchial blood flow is conspicuously increased. This blood flow from the left

[a] In these affected lungs, simultaneous measurement of the bronchial blood flow and the pulmonary blood flow has been attempted [illegible]

[illegible] venous admixture, [illegible] physiologic [illegible] monary blood flow is classified and its significance is studied (Table 13-9) The results shown are from one of the cases with silicotuberculosis

ventricle enters the lung via branches of the aorta and returns to the left ventricle via the pulmonary veins. In the discussion of the cardiopulmonary dynamics in such diseases, the bronchial blood flow plays an important role The left and right cardiac outputs of patients with pulmonary diseases should be carefully determined, with proper consideration of the special nature of the bronchopulmonary circulation.

CRITICAL ANALYSIS OF THE LEFT AND RIGHT CARDIAC OUTPUTS

When there is no shunt or abnormality in pulmonary blood flow, the cardiac outputs from the two ventricles are considered to be equal Cardiac output is calculated by Fick's principle according to the following equation:

$$\text{Cardiac output} = \frac{O_2 \text{ intake}}{\left\{\begin{matrix}\text{arterial } O_2 \text{ content} \\ - \text{ mixed venous} \\ O_2 \text{ content}\end{matrix}\right\}} \qquad (1)$$

Strictly speaking, in normal lungs, the left and the right cardiac outputs are different because of the existence of bronchial arteries and thebesian vessels. However, this theoretic difference is minimal and is within the margin of error of cardiac output measured by cardiac catheterization. Therefore, in the normal lung, the left and right cardiac outputs are considered practically equal

In the above-mentioned diseases, the bronchial blood flow which returns to the left atrium occasionally amounts to over 2 liters (over 30 per cent of cardiac output). Consequently, cardiac outputs from the left and right ventricles will be different. The left cardiac output in Eq. (1), based on Fick's principle, does not include the bronchial blood flow which supplies blood to the lung and returns to the pulmonary veins, bypassing the right atrium The right and left cardiac outputs should, therefore, be corrected in the following way

Right cardiac output = (cardiac output based on Fick's principle) − (bronchial blood flow which drains into pulmonary veins and blood flow of the thebesian vessels)

Left cardiac output = (cardiac output based on Fick's principle) + (bronchial blood flow)

The right cardiac output based on Fick's principle will actually show a value less than that which includes the blood flow of the bronchial and thebesian vessels The blood flow of the bronchial and thebesian vessels cannot be measured at present However, its value is negligible

The results of the left and right cardiac outputs measured in cases with *silicosis* and *bronchiectasis* are shown in Tables 13-11 and 13-12. When the right cardiac output is presumed to be 100, the left cardiac output will be 106 to 198 (average 131). Obviously, the right and left cardiac out-

This finding can be verified by the following experiment. When the pulmonary artery of a dog is ligated, the bronchial arteries will develop considerably. Using the bubble flowmeter technique, the bronchial arterial blood flow was directly measured in a dog with ligation of the pulmonary artery for 5 months, it showed 17.8 ml/min, or 14.2 times as high as that of a normal dog. Using the bronchospirometric method of Bloomer et al., the effective bronchial blood flow, after a lapse of time, was found to be increased in dogs with preligated pulmonary artery. The left and right cardiac outputs were found to be remarkably different within 5 to 8 months (Table 13-13).

In another experiment on *pulmonary embolism*, the bronchial blood flow was found to be not increased at the beginning of the episode, but it increased gradually to 50 ml/min after 3 months. Clinically, this was confirmed in a case with pulmonary embolism

In *chronic lung diseases*, a large amount of blood flow from the bronchial artery will drain into the lung, which will increase blood return to the left atrium Consequently, *the left ventricle has to expel more blood than the right.* Such strain will eventually cause left ventricular hypertrophy.

The development of the bronchial vascular

system and the increase of left ventricular output unquestionably play an important role in determining left ventricular hypertrophy. On the other hand, the influence of the blood pressure of the bronchial artery upon the pulmonary circulation, in parallel with the development of anastomosis between the two arterial systems has been pointed out as a contributory factor in causing right ventricular hypertrophy. It can be easily understood that the development of the bronchial vascular system in chronic pulmonary diseases is actually placing an additional burden upon both ventricles.

In the discussion of cor pulmonale in chronic pulmonary diseases, pulmonary emphysema was omitted. This condition will be the object of a subsequent study.

Right heart catheterization in chronic cor pulmonale

T. K. LIN

In order to understand the pulmonary hemodynamic changes that occur in chronic cor pulmonale, the dual pulmonary blood supplies of the pulmonary and bronchial arteries should be studied first.

Each bronchial artery courses along the posterior wall of its bronchus and enters the hilum of the lung. Its branches supply arterial blood to the bronchi, bronchioles, tracheobronchial and interbronchial lymph nodes, and the vasa vasorum of the pulmonary arteries

The common venous return for these two arterial systems of the lungs is by way of the pulmonary veins. However, the blood supply to the pleura, hilar, and mediastinal structures can be divided into the following three groups:

1. The visceral pleura is supplied by the visceral branches of both the pulmonary and bronchial arteries. The pulmonary veins provide venous drainage for these capillaries.

2 The hilar structures and the first- and second-order bronchi are supplied by the bronchial arteries The true bronchial veins are their venous drainage.

3. The extrapulmonary vessels, such as those of mediastinal structures, are supplied by the bronchial and mediastinal arteries. The azygos vein and its branches serve as venous drainage for these capillaries. Ultimately, the drainage of both the second and third groups is via the azygos system into the right atrium

Under normal conditions, the following anastomoses have been demonstrated. (1) capillary and arteriolar anastomoses between bronchial and pulmonary arteries, (2) anastomoses between pulmonary arteries and veins; (3) anastomoses between bronchial and pulmonary veins.

Figure 13-17 indicates the pulmonary and bronchial circulations. The dotted line represents the anastomoses present in normal lungs In normal dog lungs, about 99 per cent of the pulmonary blood supply is derived from the pulmonary arteries and 1 per cent from the bronchial arteries. Therefore, the left ventricular output is approximately 1 per cent greater than the right ventricular output. The blood flow through these anastomoses and the bronchial circulation is usually negligible under normal conditions However, in chronic pulmonary disease and in certain congenital heart diseases with inadequate pulmonary arterial blood supply (such as severe pulmonary stenosis or Fallot's tetralogy), the collateral bronchial arterial and bronchopulmonary venous systems become very extensive. Large anastomoses from these preexisting areas are greatly augmented Different types of shunts may develop. The type of shunt, degree of polycythemia, hypervolemia, presence of pulmonary hypertension, or possibly the competency of the azygos venous system, determine the extra work load upon the ventricles

Under normal resting conditions, the pulmonary arterial pressure is 25/10 mm Hg, with a mean pressure of 13 to 15 mm Hg. The mean pulmonary artery wedge pressure ranges from 3 to 12 mm Hg, depending upon whether the cardiac catheter tip is wedged posteriorly or anteriorly in a supine position.

Under moderate exercise, oxygen consumption may increase to 300 to 912 ml/min with a twofold increase of arteriovenous oxygen difference and threefold increase of cardiac output. However, the pulmonary arterial pressure

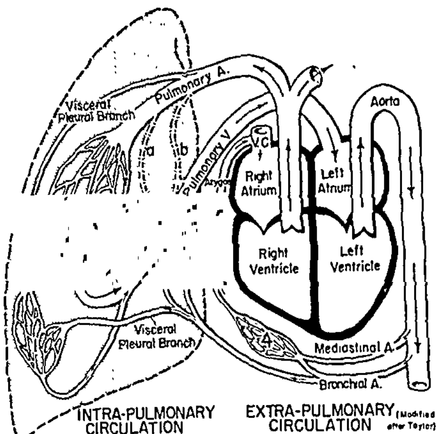

Fig. 13-17. Diagram indicating the pulmonary and bronchial circulations

shows no significant rise. Patients undergoing pneumonectomy show an average increase of 40 per cent in the systolic pulmonary pressure at the time of ligation of the pulmonary artery. The remaining pulmonary vascular bed, however, compensates for the added load in about 30 to 90 min Postpneumonectomy patients can accommodate a two- or threefold increment in the pulmonary blood flow with only a minimal increase in the pulmonary artery pressure, provided the remaining lung is normal Table 13-14 indicates the different hemodynamic changes between normal individuals and patients with chronic cor pulmonale.

In addition to the above-mentioned conditions, acute digitalization may produce a fall in the pulmonary arterial pressure in patients with chronic cor pulmonale associated with predominant left ventricular failure. The respiratory variations in pulmonary artery blood

pressure are marked in chronic cor pulmonale

The right heart pressure pattern in chronic cor pulmonale is best classified into that of right ventricular hypertrophy with or without right ventricular failure As far as the *work load* of the right ventricle is concerned, it can be due to increase of pulmonary pressure or pulmonary flow, or both When there is an increase of pulmonary flow secondary to an increase of the circulating blood volume, there is *an increase of right ventricular work, but the pulmonary pressure may not be elevated* In more advanced cases, both pulmonary hypertension and hypervolemia are usually present. The increase of blood viscosity due to secondary polycythemia may also contribute some extra work load to the right ventricle In the late stage of chronic cor pulmonale with ventricular failure, there is *a rise of right ventricular end diastolic pressure to 7 to 10 mm Hg or more,* owing to marked increase of right ventricular residual blood volume and inadequate emptying. An accompanying *functional tricuspid insufficiency* may also develop. However, *the pulmonary artery wedge pressure remains normal* throughout these stages

Various pathologic conditions which hinder effective ventricular contraction or diastolic relaxation will produce a similar right ventricular pulse pressure pattern. These conditions are constrictive pericarditis, pericardial tamponade, myocardial fibrosis, amyloidosis of the heart, other infiltrative process of the ventricle, subendocardial fibroelastosis, and right ventricular failure (other than that of chronic cor pulmonale). These conditions usually have a biventricular involvement, and the pulmonary artery wedge pressure is often elevated Figure 13-18 shows right ventricular and atrial pressure patterns simulating those of constrictive pericarditis but due to advanced chronic cor pulmonale.

In the presence of right ventricular hypertrophy, only a slight increase of the right atrial pressure occurs. The presence of a giant A wave may be explained on the basis of lesser distensibility of the hypertrophied right ventricle. The mean right atrial pressure will increase further as the right ventricle starts to fail. In the advanced stage, the increase of mean right atrial pressure can be due to (1) right ventricular hypertrophy, (2) right ventricular failure producing a high right ventricular end-diastolic pressure, or (3) functional tricuspid regurgitation.

In the early stage of chronic cor pulmonale, a mild degree of pulmonary hypertension may be present. In the late stage, a marked pulmonary hypertension usually ensues, with a compensating prolongation of the pulmonary systolic ejection phase. As the disease approaches the end of its course, the gradient between the right ventricular end-diastolic and pulmonary diastolic pressures becomes less and less.

The cardiac output in patients with chronic cor pulmonale depends on several factors.

1 Degree of pulmonary arterial resistance Some patients fail to increase cardiac output because of marked increase of pulmonary resistance These patients have a high pulmonary artery pressure.

2 Right ventricular reserve A failing right ventricle may not be able to increase the cardiac output

3 Increased circulating blood volume due to secondary polycythemia Usually, there is an increase in cardiac output if the right ventricular reserve is in good condition and there is no significant degree of pulmonary hypertension

4 Other complicating conditions, such as the status of the left heart, and other associated lesions

A few disease entities producing chronic cor pulmonale are briefly discussed below.

Chronic pulmonary emphysema has been most intensively studied. The majority of patients with a severe degree of pulmonary emphysema exhibit some degree of pulmonary hypertension The correlation between increase in pulmonary arterial pressure and the ratio of the residual lung volume to total lung volume is only moderate Cardiac index correlates inversely with the severity of pulmonary hypertension Evidence indicates that hypoxia plays a definite role in the production of the pulmonary hypertension. In most instances, administration of O_2 to patients with hypoxia and pulmonary hypertension will reduce the pulmonary arterial pressure. Cardiac output could be normal, decreased, or increased

Recently, the author has studied 10 cases of *preoperative and postoperative excision of emphysematous bullae* A transitory decline of pulmonary hypertension following bullectomy in the severe cases, with pulmonary insufficiency, hypoxia, and right heart failure, is striking However, there is a tendency to the progressive return to their preoperative level as the underlying chronic pulmonary emphysematous process proceeds Pulmonary function studies are not altered by the surgical excision

Liebow et al. (1949, 1950) have demonstrated a definite *left-to-right shunt from the bronchial arteries to the pulmonary arteries* in chronic bronchiectasis by obtaining a highly oxygenated blood sample in the pulmonary artery. This shunt will increase the left ventricular work, provided the pulmonary arterial pressure remains normal

The characteristic changes in *pulmonary capillary alveolar block* are the following Reduction of lung volume, maintenance of a large maximum breathing capacity, hyperventilation at rest and during exercise, nearly normal resting arterial O_2 saturation, marked arterial O_2 desaturation after exercise, normal alveolar O_2 tension, reduced O_2 diffusion, and pulmonary hypertension. Carbon dioxide *is* twenty-five times more diffusible than O_2 Therefore, a significant CO_2 diffusion barrier cannot exist without a fatal block to O_2 transfer. Carbon dioxide retention and *respiratory* acidosis are frequent clinical entities but always result from ventilatory or distributional *abnormalities* and not from pure diffusion difficulties.

Recurrent pulmonary embolism will produce a clinical picture of cor pulmonale. As the disease progresses, marked pulmonary hypertension associated with decrease in cardiac output, systemic peripheral vascular constriction, increased arteriovenous O_2 difference, and peripheral blotching will occur. Cardiac arrhythmias may be the terminal event. Primary pulmonary hypertension may give a similar picture, as in some cases of chronic recurrent pulmonary embolism

Polycythemia of obesity is a type of chronic cor pulmonale which is due to pulmonary alveolar hypoventilation, secondary to massive obesity This condition is characterized by arterial hypoxia and CO_2 retention, causing a variable degree of cyanosis and heart failure. The pulmonary arterial pressure varies from a slight to a moderate elevation, with normal pulmonary artery wedge *pressure, and an increase* of blood volume mainly due to increase *of red cell mass* A marked variation of peripheral arterial O_2 saturation is correlated with respiratory change. A fall arterial O_2 saturation can be achieved after inhalation of 100 *per cent* O_2. *These* abnormal changes will reverse to normal after a satisfactory weight reduction.

Different pharmacologic agents alter the pulmonary hypertension Administration of aminophylline, Priscoline, hexamethonium, *tetraethyl*ammonium bromide, sodium nitrate, dibenamine, or inhalation of 100 per cent O_2 will somewhat reduce pulmonary hypertension. In normal individuals, the infusion of *acetylcholine* into the main pulmonary artery at a rate of 0.5 mg/min causes a slight or *questionable* fall in pulmonary artery pressure. However, if pulmonary hypertension is due to hypoxia, the fall in pressure due to acetylcholine is very significant There is no change in either pulmonary *artery* wedge pressure or cardiac output. The administration of dihydroergotamine or acute anoxia will increase the pulmonary arterial pressure Intravenous injection of epinephrine gives rise to a transitory elevation of pulmonary arterial pressure. Papaverine, *given by* the intravenous route, causes no appreciable changes in the pulmonary arterial pressure In other words, an ideal satisfactory pulmonary antihypertensive agent has not yet been discovered

Roentgenology of cor pulmonale

FELIX G. FLEISCHNER

ACUTE COR PULMONALE

While the concept of chronic cor pulmonale goes back to observations by pathologists of hypertrophy and dilatation of the right ventricle in the presence of chronic pulmonary disease, the idea of acute cor pulmonale, a transient functional condition, was conceived by clinicians (McGinn and White, 1935). It is based on the concept of acute pulmonary hypertension and its reflection upon the heart. Acute cor pulmonale has been connected almost exclusively with pulmonary embolism. However, an analogous cardiovascular condition had been observed in rare cases with severe exacerbation of bronchial asthma (Turiaf et al).

A single episode of pulmonary embolism without infarct formation, if not fatal, often does not leave permanent gross morphologic changes. Roentgenologically, accordingly, the condition of acute cor pulmonale is usually believed not to be recognizable There are, however, a few roentgen observations which belong to this entity. Westermark (1938) has described a lack of blood filling of the lung of lobar or segmental extent causing increased translucency, more recently called *oligemic lung*. This observation has been confirmed by others. Why this sign is not manifest more commonly or could not be confirmed in the experimental animal is not understood, but this does not invalidate its correctness and value, when present.

The *plump, tumor-like hilar shadow* is another possible sign. Hanelin and Eyler have analyzed cases of massive chronic and subacute pulmonary embolism with large embolothrombi lodged in the hilar arteries. They convincingly demonstrated that these large thrombotic masses may form the core of the plump hilar shadows. Thus, pulmonary artery obstruction may play a direct important part in the syndrome of acute cor pulmonale and in the causation of the roentgen signs of oligemia of the lung fields and plump hilar shadows However, clinicopathologic correlation suggests that functional phenomena involving the pulmonary vasculature, i.e., reflexes originating from arteries lodging emboli, play a role, too. These phenomena, corresponding to Wood's vasoconstrictive and reactive pulmonary hypertension, and their roentgen signs do not permit of close roentgenpathomorphologic correlation. In a similar fashion, the acute cor pulmonale syndrome may lack a morphologic counterpart on the necropsy table This presentation follows the well-founded assumption that the embolic insult triggers reflexes in the cardiopulmonary system, involving the pulmonary vasculature (P. Wood, 1952), respiratory center, bronchi, diaphragm, etc In the endeavor to recognize pulmonary embolism, even though there may not be gross infarct formation, one learns to rely on functional roentgen signs. It is assumed that the embolic insult incites spastic contraction of medium-sized and small pulmonary arteries and arterioles This arteriospasm, acting in addition to the mechanical block, causes the extraordinary increase in pulmonary resistance and the extra load on the right ventricle.

Examination. The old clinical experience, that a patient recovering from an operation

may be seized by a fatal embolism while rising for the first time, prompts the question whether a roentgen examination for pulmonary embolism is advisable at all To answer this question one has to classify the patients into two groups, those in whom the diagnosis of embolism has not yet been made, and those in whom it has been made. The first group includes patients sent for a roentgen examination with no diagnosis or with a tentative diagnosis of upper respiratory infection, viral pneumonia, pleurisy, endemic pleurodynia, angina pectoris, convalescence from myocardial infarct, cholecystitis, left epigastric pain, etc. These patients may walk to the examination room or arrive in a wheel chair or on a stretcher because the attending physician expects important information. If on immediate inspection of the film, anything points in the direction of embolism with or without infarct, one should continue the examination by further questioning the patient, and using fluoroscopy with *spot films*, or using special standard views Thus, one may occasionally arrive at a diagnosis of pulmonary embolism at once or, more often, find suggestive hints which may lead to the clinical diagnosis later on.

In patients in whom the diagnosis of pulmonary embolism has been made on clinical grounds, anticoagulant treatment, vein ligation, or both have been started immediately Most physicians, however, are interested in a subsequent confirmation of the diagnosis and in a follow-up observation. The anticoagulant medication seems to provide sufficient protection; in several hundred such examinations, no untoward complication has occurred in the hospital in which the author works The examinations are carried out after several days of treatment with the patient sitting in his bed, on a stretcher or a stool, or standing according to the regimen prescribed by his physician and the condition of the patient.

The clinically postulated acute dilatation of the right ventricle can only rarely be recognized by the roentgenologist The pulmonary artery trunk, forming the second curve on the left in the posteroanterior view, may show a slight, seldom a marked bulge In most instances of first-episode embolism, it is difficult to recognize this bulge because there exists a wide range in the normal appearance of the second arch on the left However, during a close follow-up or if a previous roentgenogram is available for comparison, a definite trend to dilatation of the pulmonary artery can be recognized. *This is most marked between the second and the tenth days* and may subside in the following weeks. A decrease in width may permit the diagnosis of transient hypertension, i.e., acute cor pulmonale, in retrospect.

The hilar shadows are almost entirely made up of the branches of the pulmonary artery. Only the upper lobar veins cross them in somewhat confusing fashion. The right hilar arteries, and particularly those forming the lower half of the hilar shadow, present themselves best, owing to the anatomic arrangement, in a more coronal plane of the branches of the right pulmonary artery. The left branches are oriented in a more sagittal plane and are partially obscurred by the cardiovascular shadow. Thus, the lower two-thirds of the right hilar shadow presents the widths of the pulmonary artery branches in measurable fashion standing out against the air channel of the intermediary bronchus. The *absolute width* of this arterial band shadow varies individually but is fairly constant in the same subject. Increased width and convexity of the lateral contour are reliable signs of pulmonary arterial hypertension, and this change can even be quantitated to a certain degree.

The stress placed upon the right ventricle causes difficulties to the venous return Increased right ventricular pressure in itself interferes with passive filling of the ventricle and causes stagnation in the right atrium. Engorgement of the right atrium is further accentuated when decompensation sets in with increased diastolic pressure of the right ventricle, and becomes maximal if there is relative tricuspid insufficiency. This engorgement, clinically recognized by dilatation and pulsation of the neck veins and by the elevated venous pressure, is often clearly depicted on the roentgenogram by dilatation of the azygos vein and superior vena cava.

An Illustrative Case. A young man of 28 years was admitted to the hospital on June 8, 1955, with stabbing chest pain on the right, and a small amount of hemoptysis On June 15, the diagnosis of pulmonary embolism with infarct was established and heparin treatment started. The first set of roentgenograms shows the right hilar . . .

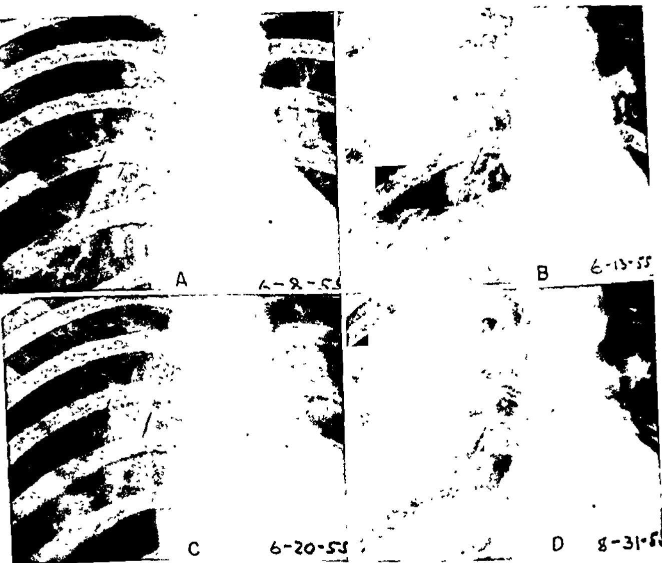

Fig. 13-19. Episode of pulmonary embolism with roentgen signs of acute cor pulmonale See text

on the day of admission measuring 11 mm in diameter (Fig. 13-19), this was followed on June 13 with a width of 14 mm, June 20 with 22 mm, and Aug. 31 with 15 mm, at a time of clinical recovery. During the early course of the disease, thrombophlebitis occurred in the left leg. The roentgenograms of June 20 show, in addition to other changes, marked dilatation of the pulmonary artery with bulging of the second left curve. The original films of this series also show definite oligemia of the lung fields (not recognizable on these reproductions). The anticoagulant treatment was discontinued on Aug 22. On Sept. 7, another embolic episode with infarction occurred The second set (Fig. 13-20) includes four roentgenograms (dated Sept 7, 26, Oct. 20, and Jan 1, 1956), with the widths of the hilar artery measuring 20, 19, 18, and 13 mm, respectively In addition to the changing width, the convex lateral bulging is distinctly visible, even more so if compared with the first and eighth roentgenograms used as a normal base line

These roentgen signs immediately connected with pulmonary hypertension may be supported by the entire roentgen symptomatology of pulmonary embolism, one or several pulmonary infarcts, pleural effusion, and inhibited ventilation characterized by high position and diminished excursion of the diaphragm, basal atelectasis (often in the form of plate atelectasis), diminished translucency of the lower lung fields, and decreased distance between the horizontal interlobe and dome of the diaphragm

Thus, in the author's experience, the condition of acute cor pulmonale, i.e , acute pulmonary hypertension, can often be diagnosed, or at least suspected, on roentgenologic evidence

CHRONIC COR PULMONALE

Cor pulmonale may be defined as the effect upon the heart of increased work load, with

or without accompanying hypoxia, caused by morbid conditions of the lung parenchyma or pulmonary vascular bed. Among them, chronic pulmonary embolism is probably a more common cause than is generally recognized (Owen et al, O'Neal et al.). Chronic pulmonary embolism, leading first to paroxysmal episodes and eventually to persistent pulmonary hypertension, is probably the purest form of cor pulmonale, possibly corresponding to Cournand's low-output form versus the high-output types, dominated by hypoxia. These cases lend themselves not only to the study of the influence of pulmonary hypertension on the heart without complicating respiratory disturbances, but also to roentgenologic recognition and analysis, because of the absence of interfering structural changes in the lung fields.

In the posteroanterior view, the cardiac silhouette has great similarity with that found in mitral stenosis (Fig 13-21). There may be only moderate left dilatation of the silhouette, or none at all. The most prominent feature is *a bulge of the pulmonary artery* forming the second curve on the left, which may reach the stage of *aneurysmal dilatation*. The prominence is often better seen in the right oblique and lateral views. In the region of the third curve, a concavity is present instead of the convexity usually seen in mitral stenosis. All other signs of left atrial dilatation, including the displacement of the barium-filled esophagus, are also absent.

Dilatation of the right ventricle, if caused by increased resistance in the *periphery* (resistance dilatation or systolic overload), involves first the outflow tract (Zdansky). The elongation of the outflow tract lifts the pulmonic valve, and both the elongation and the dilatation of this tract contribute to the prominence of the pulmonary artery. They may also cause the right ventricle to participate in the contour of the silhouette above the left ventricle. The transverse diameter of the heart in the posteroanterior view is usually not increased *in the early stages*. Only when the dilatation involves the entire right ventricle, including the inflow tract, does the silhouette widen,

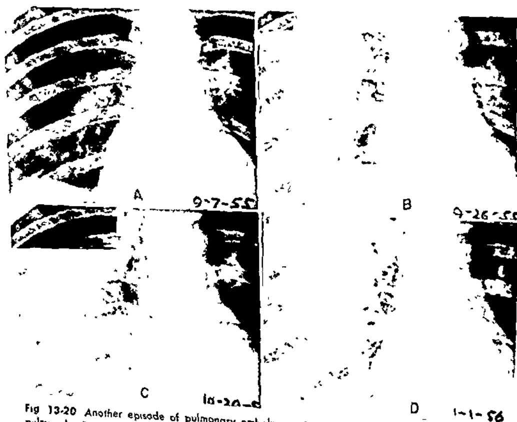

Fig 13-20 Another episode of pulmonary embolism with roentgenologic evidence of acute cor pulmonale. See text.

mainly to the left. In these instances, it may be difficult to discern whether or not there is additional left ventricular dilatation It is a common experience that dilatation of the left ventricle is assumed when none is found at autopsy. On the other hand, left ventricular dilatation may exist because of either independent preexisting heart disease or cor pulmonale. In these instances, the cardiac silhouette is usually dilated to the right. It should be mentioned that elevation of the cardiac apex, believed in the past to indicate right ventricular dilatation, has no such significance.

In the oblique and lateral views, an increase in thickness of the right ventricular wall from about 3 to 5 or 6 mm or more cannot be seen roentgenologically. On the other hand, a dilatation of the pulmonary artery, whether dynamic or organic, may be indirect evidence of ventricular hypertrophy Dilatation of the right ventricle can be assumed if, in the right anterior oblique view, the outflow tract of the right ventricle bulges forward In a similar way, the left anterior oblique view reveals an anterior bulge caused by the dilated right ventricular-atrial mass. If this bulge makes an angle of 140° or less with the supracardiac vascular contour, it can be safely assumed that it was formed in considerable part by the dilated right atrium with its appendage.

The *lateral views*, though most important, have not been given proper recognition for the assessment of the size of the right ventricle (Fig. 13-21A). In healthy persons, the area of contact between the heart and anterior chest wall, as seen on the lateral view, is usually less than a third of the distance between the sternoclavicular joint and the anterior attachment of the diaphragm This is true for a person of proportional build; chest deformities and abnormal position of the diaphragm limit the usefulness of this evaluation and should be taken into consideration.

Enlargement of the right ventricle increases the contact with the chest wall It has been objected that a normal-sized right ventricle may be pushed anteriorly by a dilated left atrium, thus obscuring the retrosternal space. This is hard to imagine on anatomic grounds and has never been demonstrated by angio-

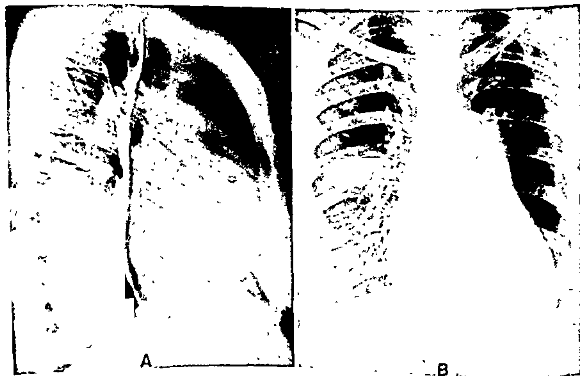

Fig. 13-21. Cor pulmonale due to chronic embolism in a 45-year-old female. Sudden onset of severe shortness of breath 1½ years before. Episodic repetition Died 2 years later. Post-mortem examination showed extreme right ventricular hypertrophy and dilatation Atheromatosis of the large branches of the pulmonary arteries Old and recent pulmonary emboli A few small fresh infarcts

cardiography. On the contrary, angiocardiography shows that a greatly hypertrophied and dilated right ventricle may cause backward displacement of the entire left heart, including the ventricle and atrium There is, however, another limitation of more academic nature It may occur that the right atrium and particularly its appendage, if dilated, may hug the right ventricle and thus add to the "area of contact." The same is true for the trunk of the dilated pulmonary artery, which may extend upwards the area of contact These conditions, however, are usually associated with right ventricular hypertrophy and dilatation Only in rare instances, such as tricuspid atresia or Ebstein's anomaly, a dilated right atrium occurs with a small right ventricle, and similarly an isolated dilatation of the pulmonary artery may occur with a normal right ventricle Thus, dilatation of the right ventricle, atrium, and pulmonary artery are usually tied together in their occurrence and functional significance, and it is of no practical consequence to discern how much each of the three components contributes to the enlarged cardiovascular body applied to the anterior chest wall such detailed morphologic analysis can be obtained only by angiocardiography.

Dilatation of the superior vena cava and azygos vein, corresponding to increased venous pressure and associated with right ventricular hypertrophy, dilatation, and failure, can be found in acute cor pulmonale

In addition to the cardiovascular silhouette, *the vascularity of the lung* fields is of diagnostic significance Prominent hilar shadows were mentioned in early descriptions of pulmonary emphysema, though their significance was not fully understood With better understanding of the pathophysiology of the pulmonary circulation has come the ability to *distinguish* the increased flow of blood to the lungs with *large arterial hilar arteries and wide peripheral pulmonary vessels* (the picture of the pleonemic lung, such as seen in the left-to-right shunts) from increased pulmonary arterial pressure with large hilar shadows and thin vascular markings (oligemic lung fields such as seen ...

te

o

s ... of the pulmonary vessels, or a combination of both In some instances of pulmonary fibrosis and emphysema, these changes are limited to the most peripheral vessels while the branches of the third to fifth order are dilated.

Vasospasm of medium-sized and small arteries has been assumed to occur in acute cor pulmonale and in mitral stenosis. A vasospastic component, in addition to intimal thickening and hypertrophy of the media, is assumed to occur also in certain congenital heart diseases with left-to-right shunt.

The roentgenologist is inclined to attribute to *arteriospasm* a considerable part in the production of the oligemic lung field. The more radiolucent background, signalizing poor blood filling of the lung at the capillary level, would be the same, whether the diminished blood flow to the lung is caused by arteriosclerotic or spastic narrowing of the arteries The roentgen beam does not distinguish between vascular wall and blood-filled lumen, an artery in which the lumen makes eight-tenths, and the wall two-tenths of the over-all cross section casts the same shadow as another artery, of the same external width, in which the lumen is reduced to two-tenths and the wall thickened to eight-tenths of the over-all width. The narrowness of the vascular shadows therefore indicates over-all thinness. The arteries may be *collapsed because* an embolus, lodged proximally, obstructs the flow But in the absence of such gross mechanical obstruction, spasm of the arteries becomes irrefutable This is *confirmed* by the experience gained in cases of mitral stenosis where marked pulmonary *hypertension* is still reversible after valvulotomy

In cases of *primary pulmonary hypertension*, the roentgen appearance suggests similar disturbances in the vascular tree The arteries of the third to fourth order down to the arterioles seem to go into vasoconstriction, thus increasing the vascular resistance The larger hilar branches, sometimes described as elastic arteries *in contradistinction* to the muscular peripheral arteries, would respond to the increased arterial pressure with dilatation

In certain instances of subacute and chronic cor pulmonale, due to pulmonary embolism, plump hilar shadows are visible They are caused by large embolothrombi lodged in the hilar arteries (Hanelin and Eyler). They seldom fill the lumen of the vessel during life,

partly because the latter is maximally dilated. A cutoff appearance of the hilar shadow or the appearance of an "amputated tail" of the hilar shadow is sometimes caused by the edge of the embolus; in other cases this optical effect is enhanced by a crossing pulmonary vein.

In many instances of chronic pulmonary hypertension, an increase of pulse pressure can be revealed by fluoroscopy as exaggerated pulsation of the pulmonary artery and the hilar arteries. The arteriospasm appears to be reversible for a considerable time. When sclerotic changes, intima thickening, and media hypertrophy occur, the condition probably becomes irreversible, as in systemic hypertension.

Cor pulmonale has been observed in young children without parenchymal pulmonary disease. It is believed that the pulmonary vasculature of these cases has retained its fetal characteristics, thus imposing an additional load upon the right ventricle. The oligemic lung fields require differentiation from those of pulmonic stenosis, while concomitant left-sided failure with pulmonary congestion may be difficult to distinguish from a pleonemic lung due to a left-to-right shunt

Differential Diagnosis. While mitral valve disease can usually be ruled out by the absence of left atrial dilatation, the various congenital abnormalities associated with dilatation of the right ventricle and pulmonary artery, and especially those with pulmonary hypertension, should be considered This includes conditions with a left-to-right shunt (atrial and ventricular septal defects, patent ductus arteriosus, aortopulmonary fistula, and right-sided implantation of pulmonary veins) These conditions cause increased pulmonary flow of blood and a pleonemic lung field They may, however, be associated with pulmonary hypertension. Such a dynamic disturbance is common in Eisenmenger's complex, can be found in ventricular septal defect (25 per cent) and patent ductus arteriosus, and is rather rare in atrial septal defect (about 10 per cent) Other conditions are isolated pulmonic stenosis and multiple local stenoses in the pulmonary artery tree.

The oligemia of the lung fields, if generalized, may suggest pulmonary emphysema However, the typical gross chest deformities, including low position of the diaphragm, are absent, no structural changes in the lung can be seen, and the ventilation of the lung (fluoroscopy, pulmonary function tests) is normal If the oligemia is unilateral and associated with smallness of the half chest and with absence of the normal hilar and peripheral vascular tree, atresia of a pulmonary artery stem may be the underlying cause. Again, if the oligemia is unilateral or limited to a lobe, occlusion of the corresponding branch of the pulmonary artery by a thromboembolus is most likely.

COR PULMONALE WITH PARENCHYMAL DISEASE OF THE LUNG

The above description dealt with chronic cor pulmonale without parenchymal disease of the lung (so-called pulmonary hypertensive heart). The situation of chronic bronchitis, pulmonary emphysema, pulmonary fibrosis, and numerous other conditions should now be discussed. The complicated interplay of respiratory, circulatory, and hematologic adjustments creates conditions quite different from those producing the pulmonary hypertensive heart This form of cor pulmonale in the older person has been termed "pulmonary hypertensive heart disease with arterial oxygen desaturation" (Hecht) or, briefly, *emphysema heart.* The combination of morphologic and functional changes prevailing in a given instance can often be determined by functional studies but is usually not apparent on roentgenologic evidence. When marked pulmonary fibrosis with emphysema is present, one may assume that the heart is affected. However, severe emphysema may occur without gross evidence of pulmonary hypertension Chronic pulmonary hypertension may manifest itself on the roentgenogram by a dilatation of the pulmonary artery and of the hilar branches while the right ventricle has not yet undergone gross hypertrophy Thus, in pulmonary emphysema the heart not only may not be enlarged or show abnormal configuration but may be *strikingly small* (Fig 13-22) This impression is often exaggerated by the low position of the diaphragm This causes, in the anterior view, elongation and median position of the cardiac silhouette and may obscure dilatation of the pulmonary artery through a counterclockwise rotation In the lateral view, the emphysematous anterior edges of the lung are interposed between heart and anterior chest

wall, thus depriving one of the yardstick of the area of contact On the contrary, in the elongated, emphysematous chest, the dilated left pulmonary artery may stand out in the left anterior oblique or lateral view, running posteriorly as a wide arc, subdividing the aortic window and forming a "double window" In similar fashion, the dilated right pulmonary artery may be recognized in this projection, in head-on view, crossing in front of the trachea Often the pattern of cor pulmonale is not obvious at first glance. The oligemia of the peripheral lung fields is often completely submerged under the consolidation of diffuse fibrosis Moreover, in advanced cases with bullous emphysema, it is impossible to say whether the obvious oligemia is part of the emphysematous destruction of the lung or the condition of secondary cor pulmonale.

Thus, it is generally accepted that a complete roentgenologic picture of chronic cor pulmonale is not always present or recognizable in parenchymatous pulmonary disease. Dilated hilar arteries and pulmonary trunk with large pulsations are sometimes the only signs suggesting chronic cor pulmonale

In chronic diseases, whenever the clinical picture or the roentgen findings point to chronic pulmonary disease, it is useful to search for the following signs of cor pulmonale: slight fullness in the region of the pulmonary artery on the left; in the presence of large hilar shadows, one should ascertain whether they are solid masses or dilated arteries (expansive pulsation on fluoroscopy). If previous roentgenograms are available, a comparison is helpful A set of films may reveal a progressive dilatation of the pulmonary artery trunk or its hilar branches, and return to normal.

Marked, chronic pulmonary *hypertension* may occur in various types of heart disease, such as hypertensive heart disease or rheumatic aortic lesions, *owing to complicating* pulmonary disease or chronic pulmonary embolism The roentgen appearance of the underlying disease is then modified by features of cor pulmonale, mostly consisting of plump *hilar arteries* and oligemia of the lung fields. In describing such a condition, one may speak of "aortic stenosis with complicating cor pulmonale"

Fig 13-22. "Emphysema heart" in a 58-year-old male. The posteroanterior view shows the prominent pulmonary artery; the left oblique view shows the "double window" The heart is small.

Circulation times in cor pulmonale

WILLIAM M. HITZIG

ASTHMA

The differentiation of cardiogenic dyspnea from bronchogenic asthma is one of the most difficult problems at the bedside, especially when the symptom manifests itself for the first time in patients in the fifth to the seventh decades of life. The simple performance of the circulation time at the bedside with Decholin, calcium, or saccharin may rapidly impart to the clinician the obvious diagnosis and allow for immediate and appropriate treatment for the relief of the asthma. Thus, a prolonged circulation time ("arm-to-tongue" time of 20 to 40 sec) in the presence of dyspnea proves it to be of cardiac origin This finding immediately counterindicates the use of epinephrine and indicates the prompt use of morphine, which, on the other hand, should not be employed in bronchial asthma In bronchial asthma, with or without severe emphysema, both the "arm-to-lung" time and the "arm-to-tongue" time may be either reduced or found to be within the range of normal circulation time.

DYSPNEA AND ORTHOPNEA

These manifestations of respiratory stress may be part and parcel of intrinsic pulmonary disease with varying degrees of associated obstructive ventilatory and diffusion insufficiencies. To differentiate from the respiratory difficulties that manifest themselves in the course of cardiac disease, the circulation time may serve as a guide in excluding the pulmonary arterial hypoxia that accompanies chronic emphysema, unilateral absence of a lung, complete unilateral pneumothorax, interstitial pulmonary fibrosis, and allied pulmonary conditions In these instances, the velocity of blood flow may actually be increased as a compensatory mechanism, and the circulation time may be either diminished or within the normal range, whereas in dyspnea or orthopnea of congestive heart failure the circulation time is prolonged

7

Primary pulmonary hypertension

DAVID T. DRESDALE

Primary pulmonary hypertension, a condition in which there is an elevated pulmonary artery pressure without a demonstrable cause, is rare, although more frequently recognized since the advent of cardiac catheterization. A more common condition is pulmonary hypertension secondary to other conditions such as rheumatic mitral valvular disease, left heart failure, chronic pulmonary disease, congenital heart disease (especially those forms with increased pulmonary blood flow), diffuse pulmonary embolism, kyphoscoliotic heart disease, and specific affections of the pulmonary vascular bed. In such cases the condition is known as *secondary* pulmonary hypertension

The etiology of primary pulmonary hypertension is not known There is considerable evidence that the increased resistance in the pulmonary vascular bed occurs in the precapillary vessels, but the cause is speculative The possibility of vasomotor activity is suggested by (1) evidence of nerve endings present in the muscular walls of small pulmonary arteries, and (2) the effect of certain drugs on the pulmonary vascular resistance. Dresdale et al (1954) and Hecht, using *Priscoline*, an adrenolytic and sympatholytic agent, observed in acute experiments a definite reduction in pulmonary vascular resistance This has also been noted by Davies et al and by Fowler et al (1950), using tetraethylammonium chloride, a ganglionic blocking agent More recently Wood (1958) and Fritts et al. (1958), brought about a reduction of the pulmonary vascular resistance in primary pulmonary hypertension, secondary pulmonary hypertension, and anoxia-induced pulmonary hypertension, with acetylcholine injected directly into the pulmonary vascular bed through a cardiac catheter. On the other hand, sympathectomy and hilar plexectomy (Griswold, Cooley—quoted from Chapman et al., 1957) did not have any beneficial effect. Hypoxia, which can cause a rise in pulmonary vascular resistance, is not a factor here since the majority of cases do not have arterial oxygen unsaturation More recently *serotonin* (5-hydroxytryptamine) has been shown to cause marked pulmonary vasoconstriction when infused into the pulmonary artery of dogs (Borst et al.). Its place, if any, in primary pulmonary hypertension has yet to be established. Edwards et al, Shephard et al., and Evans et al believe that, in some instances, there may be a persistence of a narrowed fetal pulmonary vasculature, i.e, *medial hypertrophy of the muscular arteries.* Most of the cases of primary pulmonary hypertension show pulmonary vascular changes which undoubtedly, when developed, contribute to the pulmonary vascular resistance. However, since it is felt that these lesions are secondary to pulmonary hypertension (see Chaps. 1 and 8), they are not thought of as the initiating agent in primary pulmonary hypertension.

At necropsy, all cases of primary pulmonary hypertension show marked right ventricular hypertrophy, but the changes in the pulmonary vascular bed may vary from none or minimal to marked (Dresdale et al, 1954, Soothill, Evans et al) Because of the absence of any changes in the pulmonary vascular bed, De Navasquez et al. (1940), before cardiac

Circulation times in cor pulmonale

WILLIAM M. HITZIG

ASTHMA

The differentiation of cardiogenic dyspnea from bronchogenic asthma is one of the most difficult problems at the bedside, especially when the symptom manifests itself for the first time in patients in the fifth to the seventh decades of life. The simple performance of the circulation time at the bedside with Decholin, calcium, or saccharin may rapidly impart to the clinician the obvious diagnosis and allow for immediate and appropriate treatment for the relief of the asthma Thus, a prolonged circulation time ("arm-to-tongue" time of 20 to 40 sec) in the presence of dyspnea proves it to be of cardiac origin. This finding immediately counterindicates the use of epinephrine and indicates the prompt use of morphine, which, on the other hand, should not be employed in bronchial asthma In bronchial asthma, with or without severe emphysema, both the "arm-to-lung" time and the "arm-to-tongue" time may be either reduced or found to be within the range of normal circulation time.

DYSPNEA AND ORTHOPNEA

These manifestations of respiratory stress may be part and parcel of intrinsic pulmonary disease with varying degrees of associated obstructive ventilatory and diffusion insufficiencies To differentiate from the respiratory difficulties that manifest themselves in the course of cardiac disease, the circulation time may serve as a guide in excluding the pulmonary arterial hypoxia that accompanies chronic emphysema, unilateral absence of a lung, complete unilateral pneumothorax, interstitial pulmonary fibrosis, and allied pulmonary conditions. In these instances, the velocity of blood flow may actually be increased as a compensatory mechanism, and the circulation time may be either diminished or within the normal range, whereas in dyspnea or orthopnea of congestive heart failure the circulation time is prolonged.

7

Primary pulmonary hypertension

DAVID T. DRESDALE

Primary pulmonary hypertension, a condition in which there is an elevated pulmonary artery pressure without a demonstrable cause, is rare, although more frequently recognized since the advent of cardiac catheterization A more common condition is pulmonary hypertension secondary to other conditions such as rheumatic mitral valvular disease, left heart failure, chronic pulmonary disease, congenital heart disease (especially those forms with increased pulmonary blood flow), diffuse pulmonary embolism, kyphoscoliotic heart disease, and specific affections of the pulmonary vascular bed. In such cases the condition is known as *secondary pulmonary hypertension.*

The etiology of primary pulmonary hypertension is not known There is considerable evidence that the increased resistance in the pulmonary vascular bed occurs in the precapillary vessels, but the cause is speculative The possibility of vasomotor activity is suggested by (1) evidence of nerve endings present in the muscular walls of small pulmonary arteries, and (2) the effect of certain drugs on the pulmonary vascular resistance Dresdale et al (1954) and Hecht, using *Priscoline,* an adrenolytic and sympatholytic agent, observed in acute experiments a definite reduction in pulmonary vascular resistance This has also been noted by Davies et al and by Fowler et al (1950), using tetraethylammonium chloride, a ganglionic blocking agent More recently Wood (1958) and Fritts et al (1958), brought about a reduction of the pulmonary vascular resistance in primary pulmonary hypertension, secondary pulmonary hypertension, and anoxia-induced pulmonary hypertension, with acetylcholine injected directly into the pulmonary vascular bed through a cardiac catheter On the other hand, sympathectomy and hilar plexectomy (Griswold, Cooley—quoted from Chapman et al, 1957) did not have any beneficial effect. Hypoxia, which can cause a rise in pulmonary vascular resistance, is not a factor here since the majority of cases do not have arterial oxygen unsaturation More recently *serotonin* (5-hydroxytryptamine) has been shown to cause marked pulmonary vasoconstriction when infused into the pulmonary artery of dogs (Borst et al.) Its place, if any, in primary pulmonary hypertension has yet to be established Edwards et al, Shephard et al, and Evans et al believe that, in some instances, there may be a persistence of a narrowed fetal pulmonary vasculature, i.e, *medial hypertrophy of the muscular arteries.* Most of the cases of primary pulmonary hypertension show pulmonary vascular changes which undoubtedly, when developed, contribute to the pulmonary vascular resistance. However, since it is felt that these lesions are secondary to pulmonary hypertension (see Chaps 1 and 8), they are not thought of as the initiating agent in primary pulmonary hypertension

At necropsy, all cases of primary pulmonary hypertension show marked right ventricular hypertrophy, but the changes in the pulmonary vascular bed may vary from none or minimal to marked (Dresdale et al, 1954, Soothill, Evans et al). Because of the absence of any changes in the pulmonary vascular bed, De Navasquez et al. (1940), before cardiac

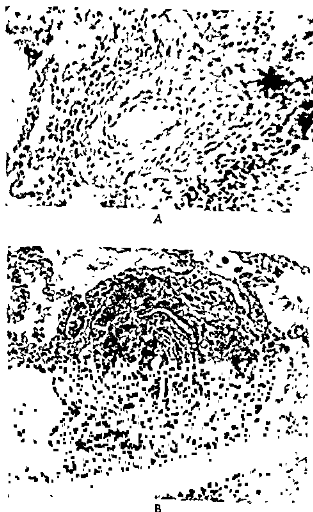

Fig. 13-23. A Fibrous intimal thickening of an arteriole of the lung. B. Occlusion of an arteriole of the lung by cellular tissue (thrombosis or intimal reaction?).

catheterization, preferred to designate their cases of isolated right ventricular hypertrophy found at autopsy, "idiopathic right ventricular hypertrophy" On the other hand, some authors called their cases "primary pulmonary vascular sclerosis" (Evans et al) or "obliterative pulmonary arteriosclerosis" (Stuckey) because of the severity of pulmonary vascular changes

The changes in the pulmonary vascular bed described below are not limited to primary pulmonary hypertension They also have been described in cases of secondary pulmonary hypertension, specifically congenital heart disease and mitral stenosis (Larrabee et al.; Edwards, Heath et al, 1955b, Parker et al, 1958) When pulmonary vascular changes occur, they are found proximal to the capillaries Predominant changes of the stem and large elastic arteries are *atheromatous lesions* It is common to find an abnormality (Heath et al, 1955a) consisting of *a distinct muscular media* in the elastic arterioles less than 100 μ in diameter (normally, in the adult, they have only a single elastic lamina between intima and adventitia). There also is fibrous intimal thickening (Fig. 13-23A), which may be severe enough to cause occlusion of the arterioles In conjunction with the above changes, there may be *medial hypertrophy in the muscular arteries*. Medial hypertrophy of the muscular arteries alone, suggesting the persistence of the fetal characteristics of the pulmonary arteries, has been described (Shephard et al, 1957, Wade et al.). At times, the muscular arteries, the arterioles, or both are partially or wholly occluded by an abnormal sparsely cellular tissue (Fig. 13-23B), which histologically may be interpreted as of thrombotic origin or as the result of intimal reaction (Evans et al). These lesions in various stages of organization have been seen in the precapillary and postcapillary vessels of microscopic size (Dresdale et al., 1951). Similar lesions have been described in 90 per cent of the cases of tetralogy of Fallot (Rich) and in pulmonary vessels of long-standing mitral stenosis with pulmonary hypertension (Larrabee et al). The question frequently and justifiably raised is whether the thrombotic lesions are related to emboli and whether they cause the pulmonary hypertension In the majority of cases reported, sites for release or discharge of emboli are not found at necropsy. It also would be very difficult to postulate multiple pulmonary emboli in young patients who develop pulmonary hypertension of unknown etiology, and in congenital heart disease, especially tetralogy of Fallot Recently Dammann et al. were able to produce similar lesions in the pulmonary vascular tree of dogs by subjecting the pulmonary vessels to a high pressure These changes were complete 11 weeks after the subclavian artery was anastomosed to the pulmonary artery of the upper lobe of the left lung. *Medial necroses* have also been reported in muscular pulmonary arteries and pulmonary arterioles (Heath et al, 1957) *Necrotizing arteritis* was noted by Shephard et al. (1957) in two cases, and was thought to be secondary to the presence of pulmonary hypertension. Similar changes have been described in four cases of

right ventricular failure of unknown etiology (Mc Keown), in the pulmonary hypertension of Eisenmenger's complex (Mc Keown; Symmers), and in pulmonary hypertension secondary to mitrol stenosis (Parker et al., 1936, Dammann et al). In view of the evidence that changes in the pulmonary vascular bed may occur when there is pulmonary hypertension regardless of the cause, it would not be unreasonable to suggest that the lesions of the pulmonary vascular bed in primary pulmonary hypertension are *the result*, rather than the cause, of the elevated pulmonary artery pressure

Primary pulmonary hypertension has been found in all age groups, having been described in patients as young as 20 months and as old as 74 years The majority of patients, however, are under the age of 40, mainly in the 20- to 40-year-old age group The *sex* incidence is predominantly female. A *familial tendency* is suggested by the findings of this disease in a woman, her sister, and her son (Dresdale et al., 1954) A brother of the woman was reported to have died of an undiagnosed heart disease at an early age

Although there are no symptoms specific for primary pulmonary hypertension, there is a group of symptoms that should raise suspicion of the presence of this disease The predominant symptoms in order of frequency of occurrence are (1) exertional dyspnea and weakness, (2) substernal and left chest pain simulating coronary insufficiency, (3) exertional syncope, and (4) palpitation Exertional dyspnea and weakness, usually the first and dominant symptoms, may be related to the decrease of right heart reserve Heath et al. (1955a) suggest that the dyspnea is due to anatomic changes in the pulmonary vessels. Some cases have been reported, however (Wittenborg, McGuire et al ; Soothill; Evans et al), in which these symptoms were present but in which no significant changes in the pulmonary vascular bed were found at necropsy *An anginal type of pain*, occurring in approximately 25 to 30 per cent of the patients, is frequently associated with exertion but may occur at rest (Evans et al). This chest pain is not limited to patients with primary pulmonary hypertension. It occurs also in other diseases with the secondary type of pulmonary hypertension (Viar et al ; Stuckey) and in patients with isolated right ventricular hypertrophy secondary to pulmonic stenosis (Stuckey, Lowance et al.; Abrahams et al ; Lasser et al). A decreased cardiac output and inadequate coronary blood flow during exercise (Dresdale et al , 1951; Stuckey) may be the explanation for this, since coronary artery disease is not found at autopsy. The decrease in cardiac output on exertion is also associated with a marked increase in the right ventricular diastolic pressure, which would further cause an increase in resistance to coronary blood flow in the right ventricle during diastole. The existence of precordial pain in the presence of pulmonic stenosis would not support the thesis that it is caused by distention of the pulmonary artery due to high tension (Viar et al.). *Exertional syncope* (Dresdale et al , 1951; Dressler; Evans et al), occurring in at least 25 per cent of the patients, appears to be related to acute right heart failure and cerebral ischemia. Cardiac arrhythmias are rare, but occasionally atrial fibrillation is present terminally. Orthopnea and paroxysmal dyspnea have been described (Evans et al.) but are unusual. When orthopnea, paroxysmal dyspnea, or hemoptysis is present, the diagnosis of primary pulmonary hypertension must be held in abeyance, since pulmonary edema does not occur in these patients. When pulmonary infarction is found, embolic phenomena must be considered.

The pertinent *physical findings* are limited to the heart and those organs affected by an elevated venous pressure as a result of right heart failure. *Right ventricular hypertrophy*, characterized by increased retrosternal dullness, widening of the conus area, and a distinct pulsating bulge of the precordium most marked along the left margin of the sternum, is always present. *The second pulmonic sound is markedly accentuated and usually split.* Early in the disease there may be no murmurs. When they occur later, there may be *a blowing systolic murmur over* the apex and precordium, owing to relative tricuspid insufficiency, and over the pulmonic area, due to a dilated pulmonary artery. A *diastolic murmur* in the pulmonic area and along the left sternal border (*Graham-Steell murmur*) can be heard in a large number of cases because of a functional pulmonary valvular insufficiency due to dilatation of the pulmonary valve ring Occasionally, a diastolic murmur or a diastolic

Fig. 13-23. A. Fibrous intimal thickening of an arteriole of the lung. B. Occlusion of an arteriole of the lung by cellular tissue (thrombosis or intimal reaction?).

catheterization, preferred to designate their cases of isolated right ventricular hypertrophy found at autopsy, "idiopathic right ventricular hypertrophy." On the other hand, some authors called their cases "primary pulmonary vascular sclerosis" (Evans et al) or "obliterative pulmonary arteriosclerosis" (Stuckey) because of the severity of pulmonary vascular changes.

The changes in the pulmonary vascular bed described below are not limited to primary pulmonary hypertension. They also have been described in cases of secondary pulmonary hypertension, specifically congenital heart disease and mitral stenosis (Larrabee et al.; Edwards; Heath et al., 1955b, Parker et al., 1958) When pulmonary vascular changes occur, they are found proximal to the capillaries. Predominant changes of the stem and large elastic arteries are *atheromatous lesions.* It is common to find an abnormality (Heath et al, 1955a) consisting of *a distinct muscular media* in the elastic arterioles less than 100 μ in diameter (normally, in the adult, they have only a single elastic lamina between intima and adventitia). There also is fibrous intimal thickening (Fig. 13-23A), which may be severe enough to cause occlusion of the arterioles In conjunction with the above changes, there may be *medial hypertrophy in the muscular arteries.* Medial hypertrophy of the muscular arteries alone, suggesting the persistence of the fetal characteristics of the pulmonary arteries, has been described (Shephard et al, 1957, Wade et al.). At times, the muscular arteries, the arterioles, or both are partially or wholly occluded by an abnormal sparsely cellular tissue (Fig. 13-23B), which histologically may be interpreted as of thrombotic origin or as the result of intimal reaction (Evans et al). These lesions in various stages of organization have been seen in the precapillary and postcapillary vessels of microscopic size (Dresdale et al, 1951). Similar lesions have been described in 90 per cent of the cases of tetralogy of Fallot (Rich) and in pulmonary vessels of long-standing mitral stenosis with pulmonary hypertension (Larrabee et al.). The question frequently and justifiably raised is whether the thrombotic lesions are related to emboli and whether they cause the pulmonary hypertension In the majority of cases reported, sites for release or discharge of emboli are not found at necropsy. It also would be very difficult to postulate multiple pulmonary emboli in young patients who develop pulmonary hypertension of unknown etiology, and in congenital heart disease, especially tetralogy of Fallot. Recently Dammann et al. were able to produce similar lesions in the pulmonary vascular tree of dogs by subjecting the pulmonary vessels to a high pressure. These changes were complete 11 weeks after the subclavian artery was anastomosed to the pulmonary artery of the upper lobe of the left lung *Medial necroses* have also been reported in muscular pulmonary arteries and pulmonary arterioles (Heath et al, 1957). *Necrotizing arteritis* was noted by Shephard et al. (1957) in two cases, and was thought to be secondary to the presence of pulmonary hypertension. Similar changes have been described in four cases of

tion curves (Shephard et al, 1957) unless there is a patent foramen ovale or bronchopulmonary anastomoses The pulmonary "arteriolar" resistance is very high. Figure 13-24 demonstrates the hemodynamic data obtained in three patients with primary pulmonary hypertension, the diagnosis being confirmed by necropsy in two of them

The *electrocardiogram* shows changes characteristic of right ventricular hypertrophy as well as evidence of right atrial hypertrophy.

The *x-ray findings* (Fig 13-25) are similar to those in conditions with right ventricular hypertrophy and diminished pulmonary blood flow without evidence of pulmonary parenchymal disease The characteristic findings are (1) right ventricular enlargement, (2) bulging pulmonary artery segment, (3) prominent hilar vessels, and (4) normal or decreased intrapulmonary vascular markings There should be no evidence of left atrial enlargement Overlapping of the spine by the cardiac silhouette may occur in the left anterior oblique view, but this in the presence of marked right ventricular hypertrophy does not necessarily denote left ventricular enlargement At autopsy, the patient whose x-rays are shown in Fig 13-25 had a normal left atrium, left ventricle, and mitral valve.

The disease generally runs a malignant *course* of from 5 months to 5 years, with the average course of 2 to 3 years after the onset of congestive heart failure Cases are reported in which the patient lived as long as 7 (Evans et al) and 15 years (Mc Callum) The course is usually progressively downhill, it is characterized by right heart failure, not infrequently terminating in sudden death. These patients do not tolerate procedures well Deaths have been reported during or following cardiac catheterization (Schafer et al; Cutler et al.); after other procedures, such as determination of decholin circulation time, angiocardiography (Cutler et al.), and simple exercise test (Wade et al); and during induction of anesthetics (Inkley et al).

Primary pulmonary hypertension should be differentiated from any condition in which there is evidence of right ventricular hypertrophy, pulmonary hypertension, and clear lung fields.

Cardiac catheterization is helpful in eliminating cases of acyanotic congenital heart lesions with pulmonary hypertension and pulmonic stenosis with poststenotic dilatation of the pulmonary artery. *Dye-dilution curves* made at the time of cardiac catheterization or angiocardiography can exclude most of the cyanotic congenital heart disease cases, except for those with an interatrial septal defect and reversed (*right-to-left*) *shunt*. It is extremely difficult to differentiate primary pulmonary hypertension with patent foramen ovale and right-to-left shunt from interatrial septal defect with right-to-left shunt, unless the latter, during cardiac catheterization, also exhibits a left-to-right *shunt*.

Recurrent pulmonary emboli and conditions in which there is specific involvement of the pulmonary vessels, such as parasitic infestations (schistosomiasis), lymphangitic carcinomatosis, and necrotizing pulmonary arte-

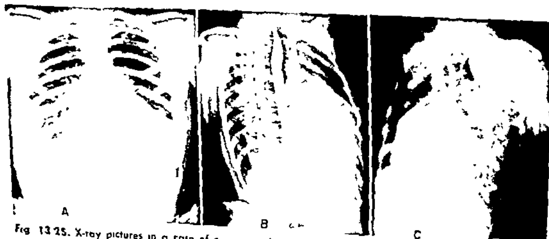

Fig 13-25. X-ray pictures in a case of primary pulmonary hypertension confirmed by autopsy.

3d sound resembling a mitral opening snap is present at the apex These sounds can be easily differentiated from that heard in mitral stenosis by means of phonocardiography. Since all the patients eventually develop congestive right heart failure, protracted neck vein distention, with visible giant A waves, is present and associated with hepatomegaly. Frequently, there is a pronounced *presystolic liver pulsation,* which becomes even more pronounced when fused with the systolic pulsation in the presence of tricuspid insufficiency. Peripheral edema may appear late (Dresdale et al, 1951). The peripheral arterial pulse is of poor volume or normal. The systemic blood pressure is always normal or low. Various degrees of *cyanosis* without clubbing of the toes or fingers may be seen This cyanosis is usually unassociated with arterial hypoxemia and is the result of an increased arteriovenous oxygen difference due to decreased cardiac output When arterial unsaturation occurs, it is the result of either a patent foramen ovale with right-to-left shunt or of a shunt through large bronchopulmonary anastomoses (Evans et al).

Routine laboratory findings are normal except for occasional *slight polycythemia.* Pulmonary function results are generally within normal limits.

Hemodynamic studies at rest utilizing the technique of right heart catheterization show (1) markedly elevated pulmonary artery pressure; (2) normal pulmonary arterial "wedge" pressure, (3) normal or low systemic artery pressure; (4) elevated right ventricular end-diastolic pressure, frequently present before clinical signs of right heart failure, (5) low cardiac output; (6) increased arteriovenous oxygen difference; (7) normal arterial oxygen saturation; and (8) normal arterial dye-dilu-

Clinical aspects of cor pulmonale

Acute Cor Pulmonale
Chronic Cor Pulmonale

IRVING MACK

ACUTE COR PULMONALE

Acute cor pulmonale may be defined as acute right heart "strain" caused by a sudden marked increase in the work demanded of the right ventricle, left ventricular failure being excluded This increased work ordinarily results from *an abrupt increase in resistance to blood flow in the pulmonary circulation* Although the commonest cause of acute cor pulmonale is pulmonary embolism (McGinn and White, 1935), the two terms should not be used interchangeably *Pulmonary embolism does not always cause acute cor pulmonale* Furthermore, there are other causes for acute cor pulmonale besides pulmonary embolism Any condition imposing a sudden increased load (input as well as output) on the right ventricle may cause the same hemodynamic changes, the same clinical picture, and the same electrocardiographic findings as those found in acute cor pulmonale due to pulmonary embolism Thus, acute cor pulmonale may occur in patients in whom massive destructive pulmonary disease is complicated by sudden further obliteration of the pulmonary vascular bed, such as that caused by extirpative or collapse surgery, spontaneous pneumothorax, massive atelectasis, or extensive pneumonitis (Mack et al, 1950a) *A combination of events may lead to acute cor pulmonale* Patients have been described with compression of the main pulmonary artery trunk or its major stems by a tumor, who, with the sudden onset of massive pneumonitis or extensive metastatic involvement of the remaining pulmonary tissue, developed fatal acute cor pulmonale (Mack et al, 1950a) Acute cor pulmonale has also been reported resulting from acute spontaneous mediastinal emphysema (Klein, 1947) or a sudden increase in the herniation of intestinal content through a diaphragmatic hernia (McGinn and Spear, 1941) The sudden development of a left-to-right shunt will lead to all the abnormalities recognized as acute cor pulmonale This applies to patients in whom an aneurysm of the aorta or sinus of Valsalva suddenly ruptures into the right atrium, ventricle, or pulmonary artery, and to those in whom a sudden interventricular septal perforation occurs, as in acute ulcerative bacterial endocarditis or interventricular septal rupture following an infarction.

While pulmonary emboli are usually blood clots detached from other portions of the circulatory system (various areas of the venous bed or the right chambers of the heart), acute cor pulmonale may also be caused by embolism of fat, air, amniotic fluid, or cerebral cortical tissue (Durant et al., 1947, Warren, 1946; Steiner and Lushbaugh, 1941, Oppenheimer, 1954). Acute cor pulmonale does not occur in every case of pulmonary embolism, the number and size of the emboli may be insufficient to cause the acute hemodynamic changes leading to acute cor pulmonale, or the embolization may lead to ventricular fibrillation and sudden death (Katz, 1945)

Patients surviving repeated widespread embolization of the lungs may later develop chronic cor pulmonale (Owen et al., 1953). This may occur after repeated, multiple, small pulmonary embolizations, or after occlusion, with subsequent thrombosis, of large branches

ritis, have hemodynamics similar to that found in primary pulmonary hypertension. Clinical findings, as well as lung biopsy, may be helpful

At times, the diagnosis is not established definitively until autopsy. Even then, the pulmonary vascular changes secondary to pulmonary hypertension make it difficult to separate recurrent small pulmonary emboli from primary pulmonary hypertension unless a source for the emboli is found Patients with idiopathic dilatation of the pulmonary artery do not have evidence of right ventricular hypertrophy. The elevated pulmonary artery "wedge" pressure and enlargement of the left atrium found in mitral stenosis are not present in primary pulmonary hypertension In primary pulmonary hypertension, there is no evidence of pulmonary parenchymal involvement like that found in cor pulmonale secondary to pulmonary disease.

There is no treatment, as yet, that will reverse the malignant course of the disease. *Priscoline,* 50 to 75 mg parenterally, several times a day, has temporarily improved some of the patients clinically and hemodynamically (Dresdale et al., 1951; Hecht). Thoracic sympathectomy and hilar plexectomy (Griswold, Cooley, quoted from Chapman, et al, 1957) have not been beneficial. Anticoagulant treatment, suggested by Cutler et al., could be useful if the obstructive lesions in the pulmonary blood vessels were predominantly thrombotic and not due to proliferation of intimal fibroelastic tissue. Although the response to the accepted treatment for heart failure is poor, it should be instituted when right heart failure is present.

left lateral position may be lifesaving (Durant et al., 1954).

REFLEX PULMONARY ARTERIOLAR CONSTRICTION. Obstruction of small pulmonary arteries and arterioles by showers of emboli leads to reflex arteriolar constriction, not only in the same lobe but also in the opposite lung. This parallels the situation seen in embolization of major systemic arteries (Megibow et al., 1942, De Takats et al., 1939, Laurent et al., 1956). Additional evidence for this pulmono-pulmonary reflex was obtained by Niden and Aviado by using a perfusion technique, in which one lobe of the dog's lung was supplied with blood from a donor dog. Injection of glass beads into the unperfused lobes of the experimental dog produced a reflex vasoconstriction of the perfused lobe, although the beads never reached the perfused lobe (Niden and Aviado, 1956). Mention should be made that other investigators have not demonstrated the above reflex pulmonary vasoconstriction (Daley et al., 1951; Knisely et al., 1957).

ELEVATION OF PULMONARY VENOUS PRESSURE. There is some evidence that a reflex elevation of pulmonary venous pressure may add to the increase in pulmonary vascular resistance (Aviado and Schmidt, 1955, Laurent et al., 1956).

HUMORAL MECHANISMS. It has been suggested that the liberation of chemical substances, such as serotonin, at the site of embolism may also act to increase pulmonary vascular resistance. The presence of increased circulating serotonin during embolism has been confirmed (Comroe et al., 1953, Aviado and Schmidt, 1955).

HYPOXEMIA. Hypoxemia has been shown to cause an increase in pulmonary arterial blood pressure by some, as yet, poorly understood mechanism, which is discussed below (*see* Chronic Cor Pulmonale).

The development of dilatation of the right ventricle leads to a change in position of the entire heart, *viz.*, clockwise rotation about its longitudinal axis, as well as a more vertical position (McGinn and White, 1935, Wilson et al., 1947).

Mechanism of the Production of Myocardial Ischemia. Myocardial ischemia occurs in acute *cor pulmonale* as a result of a reduction in coronary flow, hypoxemia, and an increased oxygen requirement of the heart as a result of its increased work.

REDUCED CORONARY FLOW. The reduction in the coronary arterial flow is due to multiple factors. The increased pulmonary resistance causes a rise in right ventricular pressure and dilatation of that chamber. The increased pressures within the right ventricle (and often the right atrium), by interfering with the drainage from the thebesian vessels and the coronary sinus, reduce the effective pressure gradient between the coronary arteries and their drainage systems.[1] The associated increased intramural pressure of the right ventricle, acting as an extravascular force, further impedes coronary blood flow in the walls of this chamber. Since this reduction of blood flow is most marked in the right coronary artery, the evidence of myocardial ischemia is most marked in the right ventricle and the posterior portion of the left ventricle (Katz et al., 1938; Currens and Barnes, 1943, Durant et al., 1947).

A marked *fall in systemic arterial blood pressure* has been noted to occur after pulmonary embolism, and is frequently disastrous, since it decreases the effective pressure gradient between the aorta and the coronary arteries and their drainage systems. This acute arterial hypotension is due to a combination of various factors. The immediate systemic arterial hypotension following pulmonary embolization is part of a triad caused by a Bezold-Jarisch-like reflex (apnea, bradycardia, and hypotension), possibly due to the stimulation of pressoreceptors in the heart and lung. Experimentally, it can be abolished by vagotomy (Niden and Aviado, 1956). That shock in acute *cor pulmonale* may be due to such a reflex mechanism has been demonstrated in man (Selzer and Bradley, 1957). However, the continued hypotension results mainly from the diminished output of the left ventricle, which is a consequence of the obstruction to blood flow in the pulmonary circuit (reduced left ventricular inflow) (Mendlowitz, 1938, Katz et al., 1945). Moreover, this diminished cardiac output per se decreases coronary flow. Increased pulmonary venous pressure, which has been observed

[1] Increased right atrial pressure occurs only when the diastolic pressure of the right ventricle rises. Therefore, it is evidence of right ventricular failure.

of the pulmonary artery (Hanelin and Eyler, 1951; Magidson and Jacobson, 1955; Ring and Bakke, 1955).

INCIDENCE

In most general hospitals, pulmonary embolism is found in about 10 per cent of patients at necropsy (Short, 1952; Hampton and Castleman, 1940). An even higher incidence (25 per cent) is recorded when a more selected group is studied, as in necropsies in a home for the indigent (Tobin, 1954). Clinical surveys show lower figures mainly because of the difficulties in diagnosis In some hospitals, the diagnosis of nonfatal pulmonary embolism is rarely made Israel and Goldstein report that pulmonary embolism occurred in 1.2 per cent of medical admissions and in 0.6 per cent of surgical admissions to a general hospital The frequency of pulmonary embolism is thus greater in medical patients, but it should be kept in mind that the age of this group is higher In some hospitals, pulmonary embolism is the most common acute pulmonary disease, more prevalent than lobar pneumonia or bronchogenic carcinoma (Short, 1952, Israel and Goldstein, 1957)

Pulmonary embolism occurs most frequently in those conditions associated with immobilization, venous trauma (mechanical or infectious), and the hypercoagulable state While *postoperative embolism* has been observed in patients without demonstrable predisposition, it occurs much more frequently in the presence of dehydration, obesity, heart disease, venous varicosities, previous thrombophlebitis, anemia, and neoplasm. *Thrombophlebitis*, with or without much inflammatory manifestation, predisposes to pulmonary emboli Thrombophlebitis may occur at the site of fractures, nonpenetrating injuries, and after repeated venipuncture. Predisposing to pulmonary embolism are such medical diseases as congestive heart failure, polycythemia vera, severe anemia, and neoplasm. Pulmonary embolism is much more common after the age of 40 (Israel and Goldstein, 1957).

PATHOLOGIC PHYSIOLOGY OF ACUTE COR PULMONALE

Originally, the disturbed physiology, the clinical picture, and the electrocardiographic changes of acute cor pulmonale were considered primarily a reflection of the dilatation of the right ventricle resulting from the increased burden imposed upon this chamber (McGinn and White, 1935). However, *the additional factor of myocardial ischemia, particularly of the right ventricle and posterior wall of the left ventricle, is of equal importance.* Indeed, acute or subacute myocardial necrosis of varying extent is not infrequently seen at necropsy in patients who die in acute cor pulmonale They occur only when the myocardial ischemia is sufficiently severe and prolonged. While this necrosis is reported to occur occasionally in the absence of significant narrowing of the coronary arteries, it is usually favored by (1) duration of life for several hours or weeks after the initial embolization, (2) preexisting coronary sclerosis, (3) previous hypertrophy of the heart which accentuates any coronary insufficiency (coronary flow/muscle mass disproportion) (Horn et al., 1939; Megibow et al., 1942; Dack et al., 1949).

Mechanism of the Right Ventricular Dilatation. The sudden increase in resistance to pulmonary flow in acute cor pulmonale results from the following events:

MECHANICAL OBSTRUCTION OF VESSELS The pulmonary emboli may vary in size from the large *serpentine embolus,* often coiled up and riding the bifurcation of the pulmonary artery trunk or occluding its main branches, to smaller emboli occluding the smaller pulmonary arteries, or even very minute ones plugging the arterioles The emboli often are detached from their source of origin in volleys. In pulmonary *air embolism*, the catastrophic events result from a different mechanism Death, when it occurs, is due to obstruction of the right ventricular outflow tract by an air trap which forms within it. Durant has demonstrated experimentally in dogs that turning the animal onto his left side so that the outflow tract will assume a position inferior to the body of the right ventricle permits the air trap to disappear from this now inferior position, it becomes churned into a froth which gradually disappears from the cavity of the right ventricle by being transported with the blood to the lungs, where excretion can take place This relieves the obstruction Thus, *displacement of the air trap by turning the body into the*

INCREASED OXYGEN REQUIREMENT OF THE HEART AS A RESULT OF ITS INCREASED WORK. The work of the heart in acute cor pulmonale must increase in order to overcome the greater resistance in the pulmonary circuit. Tachycardia may also further tax the heart. Since the oxygen requirement of heart muscle increases at least in proportion to the amount of work performed and the degree of dilatation (Landowne and Katz, 1944, Bing et al, 1949), the relative ischemia is intensified in the presence of a diminishing supply of oxygen to the heart. Significant *fever*, while unusual as an early manifestation of acute cor pulmonale due to embolism, frequently occurs later and tends to increase the oxygen requirements of the peripheral tissues as well as those of the heart.

It is the ultimate inability of the heart to meet these increased demands for work in the presence of relative ischemia that eventually results in failure and death in acute cor pulmonale

Elliott and Beamish have pointed out that *in the presence of a patent foramen ovale, pulmonary embolism may cause a right-to-left shunt through the defect which serves to alleviate the effects of the embolism* The full clinical sequence consists of pulmonary embolism, followed by a variable period of improvement (the "palliative-shunt" phase), and finally by sudden death when the shunt is occluded In its most recognizable form, the shunt phase is characterized by pallor, cyanosis unrelieved by oxygen, hypotension, profuse perspiration, moderate venous distention, and absence of the usual electrocardiographic changes seen in acute cor pulmonale During this phase, *peripheral paradoxic embolism* may occur because there is a functioning interatrial shunt with a sizable right-to-left flow of blood In the reported cases, death was precipitated by acute cor pulmonale as a consequence of sudden obstruction of this decompressive shunt between the right and left atria, and not to further pulmonary embolism, as had been supposed (Elliott and Beamish, 1953)

DEVELOPMENT OF PULMONARY INFARCTION

Nutrient requirements of pulmonary tissue distal to an embolus may be supported by the pulmonary arterial circulation through capillary anastomoses in the pulmonary capillary bed The bronchial arterial circulation is not necessary for this purpose (Karsner and Ghoreyeb, 1913). It has been observed clinically and confirmed experimentally that *pulmonary congestion favors the development of pulmonary infarction* after pulmonary embolism (Chapman et al., 1949). However, even in the absence of pulmonary venous congestion, when sufficient emboli are present to produce complete obstruction of the pulmonary arterial blood supply to a segment of pulmonary tissue, or if a large enough pulmonary artery is occluded, infarcts do occur (Steinberg and Mundy, 1936). When fewer emboli are discharged, instead of true pulmonary infarcts, lesions exhibiting the edema, alveolar hemorrhage, and leucocytic infiltration, corresponding to the "incomplete infarcts" are encountered (Hampton and Castleman, 1940). The *bronchial arterial circulation* is an important contributing factor to the development of hemorrhage into pulmonary tissue after pulmonary embolism. However, experimentally, if sufficiently severe pulmonary venous congestion is present, pulmonary infarcts develop even after the bronchial arteries are occluded to the area before the emboli are produced (Ellis et al, 1952a) Since infection frequently helps to cause excavation and the production of *infarct cavities*, it is important to use antibiotic therapy in patients with pulmonary embolism Infected pulmonary infarcts, because of their contiguity with pleural surfaces, are not infrequently complicated by the development of *empyema*

CLINICAL FINDINGS

The clinical picture of pulmonary embolism may vary greatly While embolization of the lung may be entirely *silent*, a high index of suspicion in the examiner will permit the diagnosis to be made much more frequently than heretofore reported Important are the size, number, location, and frequency of recurrence of the [illegible]

[illegible]

[illegible] *of pulmonary infarction.*

Manifestations of pulmonary embolism include dyspnea, tachypnea, retrosternal *pressure* pain, tachycardia, signs of cerebral *ischemia* (restlessness, syncope, convulsions) [illegible]

experimentally in pulmonary embolization, is known to cause peripheral vasodilatation by a poorly understood mechanism, which can be abolished by vagotomy (Niden and Aviado, 1956). Prolonged hypoxemia also contributes to the peripheral circulatory collapse.

While not usually recognized clinically, *bradycardia* develops immediately after embolization. This is a result of a Bezold-Jarisch-like reflex, as well as a result of the stimulation of pressoreceptors in the trunk of the main pulmonary artery (Niden and Aviado, 1956). *Tachycardia* soon supervenes and becomes one of the most outstanding and persistent clinical findings. It is a result of the hypoxemia and of reflexes arising from stimulation of carotid and aortic receptors Although initially of compensatory value, tachycardia may lead ultimately to a further reduction in cardiac output and so, secondarily, to a diminution of the coronary flow by decreasing the duration of diastole

Various reflexes, which directly diminish coronary flow in acute cor pulmonale, have also been described. However, the existence of a so-called *pulmonocoronary reflex*, in which reflex vagal coronary vasoconstriction is allegedly produced by the sudden obstruction to flow in the pulmonary arteries (Scherf and Schonbrunner, 1937, Eckhardt, 1938), has not been confirmed (Megibow et al , 1942; Malinow et al., 1946; Hackel et al , 1954) On the other hand, a *pulmonopulmonary reflex*, in which pulmonary emboli are accompanied by a reflex vasoconstriction of other branches of the pulmonary arteries without intraluminal obstruction, has been demonstrated experimentally and has been discussed above.

HYPOXEMIA Hypoxemia in acute cor pulmonale results from a combination of causes While the existence of *precapillary shunts* between the pulmonary arteries and pulmonary veins has been recognized for some time (Tobin and Zariquiey, 1953), their possible importance in causing hypoxemia very early after pulmonary embolism has been evaluated only subsequently. Niden and Aviado have demonstrated experimentally that the passage of large glass beads (420 μ in diameter) through these shunts was facilitated by increasing pulmonary arterial perfusion pressure, and was hindered by ventilation with 100 per cent oxygen. This marked lability of the pulmonary shunts suggests that pulmonary embolism, by increasing pressure in the pulmonary arterial tree, opens them, thus aggravating the concomitant hypoxemia and at the same time minimizing the rise in pulmonary artery pressure. The hypoxemia, which is aggravated by these shunts, also acts to keep them open. Diminished oxygenation of the blood may also occur as a result of a reduction in pulmonary blood flow. The peripheral circulatory collapse described earlier favors *stagnant hypoxia* in the peripheral tissues.

Despite certain theoretical considerations, *pulmonary edema* has been reported in acute cor pulmonale. This may result from the peripheral circulatory collapse which may follow acute cor pulmonale, since pulmonary edema has been observed in dogs following acute peripheral blood loss and shock (Eaton, 1947). However, there is also evidence that reflex pulmonary venoconstriction contributes not only to the elevation of pulmonary resistance as described above but also to the production of pulmonary edema (Laurent et al, 1956, Niden and Aviado, 1956). Pulmonary edema will interfere with the diffusion of oxygen across the alveolar-capillary barrier and thus will contribute to the hypoxemia (see Part 18, Chaps. 12 and 13)

A *pulmonobronchomotor reflex* causing bronchospasm has been described following embolization. However, experimental methods for measuring bronchomotor tone are likely to record blood volume changes in the lungs, so that true bronchomotor responses are difficult to distinguish from vascular changes (Barer and Nusser, 1953). However, if bronchoconstriction occurs, it would contribute to the hypoxemia, as well as tend to increase resistance to blood flow through the lungs. The dyspnea and tachypnea occurring in pulmonary embolism are well recognized The changes in respiratory frequency and depth which occur after pulmonary embolism are complex and result from many influences and reflexes. *Hypoxemia*, if present, contributes to the reflex production of tachypnea, but tachypnea occurs even in the absence of hypoxemia, or if the hypoxemia is corrected (Megibow et al., 1942 and 1943; Whitteridge, 1950; Niden and Aviado, 1956). However, there is no good evidence that inefficient ventilation contributes to the hypoxemia.

precordium. When inversion is limited to lead V_2, it may be due to extreme clockwise rotation of the heart. When the T-wave inversion extends to leads V_3 and V_4, it may be a reflection of myocardial ischemia or of the poorly understood phenomenon of acute right ventricular strain. Contrary to the pattern in anterior-wall infarction, abnormal elevation of the S-T segments in the precordial leads usually does not occur, except occasionally in leads V_1 and V_2

c Development of a Q wave with inversion of the T wave in lead III Contrary to earlier reports in acute cor pulmonale, a small Q wave is either present (vertical position of heart) or absent (semihorizontal position of heart) in lead aVF. In the latter case, the Q_3T_3 pattern is related to the fact that the R and T waves are taller in aVL than in aVF. Lead III, which is roughly equivalent to (aVF − aVL) × ⅔, will as a consequence show a Q wave and an inverted T wave (Myers and Oren, 1945). Whether the reduction in amplitude of R and T waves in aVF is partially due to severe ischemia of the diaphragmatic surface of the heart, or is merely a result of changes in the heart's position is not known at this time Contrary to the usual pattern in posterior-wall myocardial infarction, *a Q wave and an inverted T wave are usually not present in lead II* The vectorcardiogram further aids in differentiating acute cor pulmonale from posterior-wall myocardial infarction.

d Development of so-called *incomplete or even complete right bundle branch block* with a late R' in the leads from the right precordium This may appear early or late after the onset of acute cor pulmonale, it may be transient or permanent (Durant et al, 1939) This apparent conduction defect in the right ventricle may be due to the mechanical effect of the sudden marked dilatation of the right ventricle and the ischemia of the right ventricular myocardium

e Development of a *P pulmonale* (tall P wave in leads II and III, sharply diphasic P wave in V_1 to V_2)

f Sinus tachycardia is almost always present. *Arrhythmias* of almost any type

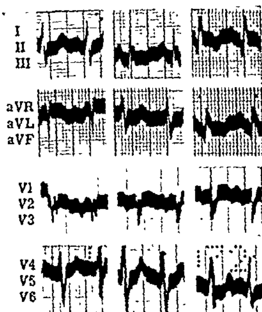

Fig. 13-26. Acute cor pulmonale due to massive pulmonary embolism 10 days after cholecystectomy in a 50-year-old female patient. Sinus rhythm. S waves are present in leads I, aVL, and V_6. S-T depression of the "staircase variety" is present in leads I, aVL, V_5, and V_6. Q and inverted T waves are present in leads III and aVF. R wave is very small in leads V_2 and V_3 T wave is inverted in leads II and III. The transitional zone over the precordium is shifted to the left Discussed in text.

are very frequent. They may be produced reflexly, and hence are neurogenic in origin. They may also be due to ischemia of the myocardium leading to areas which act as ectopic foci for the origin of ectopic rhythms, or to areas in which conduction is critically slowed to permit the development of reentry mechanisms, which then are responsible for the arrhythmias (Katz and Pick, 1956, Mack and Langendorf, 1950) The development of a *P pulmonale* is usually a grave prognostic sign (Eliazer and Giansiracusa, 1952).

The changes described may appear several hours after the episode, and usually disappear after 4 to 10 days. Persistence of the pattern may speak for repeated small pulmonary embolizations (Phillips and Levine, 1950). The evolution is not prolonged over a period of 6 to 10 weeks, as in myocardial infarction.

The above listing of the changes occurring in acute cor pulmonale is intended to include all the classic changes. It was formerly believed

right ventricular dilatation and failure, cyanosis, fever, and sudden death.

Evidences of pulmonary infarction include pleuritic chest pain with or without a friction rub, pleural effusion (often hemorrhagic), marked local chest tenderness, hemoptysis, cough, dyspnea, and tachycardia (Parker and Smith, 1958).

While *hemoptysis* and a *friction rub* have been considered the classical signs of pulmonary embolism, they are not the most common. More frequent are such nonspecific symptoms as *fever, tachycardia, pleuritic chest pain*, and *dyspnea*. Any combination of all the above symptoms and signs may be present and may mimic acute pulmonary or cardiac disease

Myocardial infarction is frequently complicated by pulmonary embolism, but pulmonary embolism may also precipitate *subendocardial myocardial infarction*, especially in a patient with coronary sclerosis. Severe *diaphragmatic pleuritis*, associated with a basal pulmonary infarct, may simulate an acute abdominal condition.

Although most emboli originate in the veins of the legs, objective evidence of *phlebitis* is present in only about 50 per cent of cases (Israel and Goldstein, 1957)

A polymorphonuclear leucocytosis and elevation of the sedimentation rate occur often Significant elevation of the serum glutamic oxalacetic transaminase level occurs only *rarely* in the absence of hepatic dysfunction, myocardial infarction, extensive lung necrosis, or muscle injuries (Goldstein et al , 1956) When elevation of transaminase levels does occur in pulmonary infarction, the values are usually lower than with myocardial infarction, and the elevation occurs relatively late (24 hr after the myocardial infarction, and 3 to 6 days after the pulmonary embolism). This determination is, therefore, frequently of value in differentiating the two conditions (Agress et al , 1956, Ostrow et al., 1956). Hyperbilirubinemia and (rarely) clinical jaundice have occasionally been observed. While, in the past, this has been attributed to hemolysis in the infarct, it is generally agreed that it is usually due to hepatic dysfunction, preexisting or due to congestion or hypotension.

ROENTGENOLOGY

The diagnosis of pulmonary embolism or infarction cannot be made from the roentgenogram alone. The x-ray may show no abnormalities, even after repeated embolizations. Occasionally, a film may show relative avascularity of the area of the lung distal to the embolus (Westermark, 1938).

If acute cor pulmonale has developed, dilatation of the main pulmonary artery and its major branches may be apparent. Usually, however, the changes in the x-ray are a result of pulmonary infarction. The infarcts are often multiple, usually appear at the bases of the lung, and are often contiguous with the pleural surfaces.

The classical wedge-shaped density with apex directed to the hilum is not usually observed; pulmonary infarcts may present any shape on x-ray, resembling patches of pneumonitis or subsegmental atelectasis. *Pleural effusion* is common, often with elevation of the hemidiaphragm; this may obscure the infarct itself. Serial films show the shadows to clear usually by contraction into linear or stellate densities, rather than by resolution. This type of evolution may help suggest the diagnosis.

ELECTROCARDIOGRAPHIC CHANGES

The electrocardiographic features of acute cor pulmonale (Fig. 13-26) may be correlated with the two main dynamic alterations which occur.

1 The development of *sudden dilatation of the right ventricle* leads to a change in position of the entire heart: clockwise rotation about its longitudinal axis, as well as the assumption of a more vertical position (McGinn and White, 1935; Wilson et al., 1947). This change in position is responsible for the appearance of deep S waves in leads I and II It also causes a shift of the transitional zone to the left in the precordial leads (Mack et al., 1950a, Weinschel et al , 1951, Eliaser and Giansiracusa, 1952)

2 The electrocardiographic changes that follow may be considered to be a reflection of *myocardial ischemia*, particularly of the right ventricle and posterior wall of the left ventricle

a. Depression of the S-T junction and segment in leads I, II, aVL, V_5, and V_6, of a type described by McGinn and White as being of the "staircase" variety.

THE CAUSES OF CHRONIC COR PULMONALE

Chronic cor pulmonale develops when the involvement (structural or functional) of the lungs or its vessels is bilateral and *diffuse*, and not *unilateral or focal* Classifications in the past have usually been based on the anatomic location of the pulmonary disease process. More useful is a classification which correlates *anatomic and functional abnormalities* and, in addition, has important therapeutic implications According to this classification, the etiology of chronic cor pulmonale may be divided into *three main groups*: type I–pulmonary diseases and dysfunction associated with chronic diffuse obstructive emphysema, type II–pulmonary diseases and dysfunction with *chronic alveolar hypoventilation*; and type III–pulmonary diseases in which the pathologic process and dysfunction are localized in or about the pulmonary vessels (see Classification of Causes of Chronic Cor Pulmonale). This classification is not rigidly exclusive, for some cases may demonstrate features of more than one type of pulmonary involvement. Therapy is usually much more satisfactory in chronic cor pulmonale of types I and II than in type III. This is so because at least some of the structural and functional abnormalities which cause the development of chronic cor pulmonale in these types are partially reversible (Mack and Snider, 1953) This reversibility will be regularly noted in the discussion to follow

In patients with chronic pulmonary disease having a markedly restricted pulmonary vascular bed, the abrupt development of some pulmonary catastrophe, such as extensive pneumonitis or massive collapse of a lung, which produces a critical increase in pulmonary vascular resistance, may cause a rapid dilatation of the right ventricle associated with myocardial ischemia and death The clinical picture, the electrocardiographic changes, and the pathologic findings will be similar to those of acute cor pulmonale, although no pulmonary embolization has occurred (Mack et al, 1950)

TYPE I: PULMONARY DISEASE WITH PREDOMINANT CHRONIC DIFFUSE OBSTRUCTIVE EMPHYSEMA

In the United States, *chronic diffuse obstructive emphysema* is by far the commonest cause of chronic cor pulmonale While there is considerable controversy about the pathogenesis of this process, there is little argument about the functional abnormalities

Chronic diffuse obstructive emphysema is associated with an absolute increase in the residual volume and functional residual capacity. There is a decrease in the vital capacity and maximum breathing capacity, the decrease of the latter being more marked. The work of breathing is greatly increased (Mc Ilroy and

that recognizable electrocardiographic changes could be found in only 10 per cent of cases of acute cor pulmonale. With the use of multiple leads, some changes which would make one suspect the presence of acute cor pulmonale are seen to occur in the majority of cases. However, only by understanding the physiologic mechanisms underlying the electrocardiographic changes can one recognize and understand the electrocardiographic picture when it presents itself in a less typical fashion.

TREATMENT

Prevention of thromboembolism has not been very successful. Early ambulation after surgical procedures has not produced a striking reduction in the incidence of thromboembolic phenomena. The application of elastic stockings to the legs of all immobilized hospital patients over the age of 20 has been of definite value (Wilkins and Stanton, 1953). The early recognition of pulmonary embolization, or phlebitis in the legs, is of paramount importance. Once thromboembolic complications have been recognized, the use of *anticoagulant therapy,* while not a perfect preventative, will greatly reduce the frequency of recurrent emboli. *Superficial femoral vein ligation* has been somewhat disappointing. *Ligation of the inferior vena cava* is frequently followed by venous insufficiency of the lower extremities. However, when anticoagulants cannot be employed, or when the discharge of emboli continues despite anticoagulants, the appropriate veins should be ligated. The shock in acute cor pulmonale is best treated by *intravenous levarterenol.* Intravenous *atropine* in high doses has been advocated to block some of the lethal reflexes but has not proved to be of striking value. Pulmonary arteriotomy with *embolectomy* has been tried, but it requires the differentiation of large emboli in the major pulmonary arteries from multiple small emboli. *Oxygen* in high concentration, and *opiates* for pain, should be administered. *Antibiotics* should be given when there is evidence of pulmonary infarction.

CHRONIC COR PULMONALE

Chronic cor pulmonale may be defined as right ventricular hypertrophy resulting from *disordered structure or function* of the lung, the pulmonary circulation, or both. Thus definition excludes such causes of right ventricular hypertrophy as left ventricular failure, constrictive pericarditis, congenital heart disease, and acquired valvular heart disease. The term "pulmonary hypertensive heart disease" has been used to include not only those conditions which fall within the strict definition of chronic cor pulmonale but also all conditions associated with pulmonary hypertension and right ventricular hypertrophy, including left ventricular failure, mitral stenosis, and various types of congenital heart disease with left-to-right shunt. The more narrow definition of chronic cor pulmonale is probably more useful and will be used in the discussion below.

The term "Ayerza's disease" was used by Arrillaga to describe a group of cases similar to one presented by Ayerza in 1901. These were cases in which right heart failure was associated with severe cyanosis, polycythemia (*cardiacos negros*), and pulmonary disease, which Arrillaga presumed was syphilitic in origin. The ambiguity of the term has been attested by the diverse meanings given it in the literature. It has been used to describe a variety of conditions, including everything from chronic cor pulmonale due to chronic obstructive emphysema with cyanosis and secondary pulmonary arteriosclerosis, to primary pulmonary hypertension. It would be best if it could be dropped from usage.

The true incidence of chronic cor pulmonale is higher not only than that given in clinical reports but also than that reported in necropsy series. The cachexia of chronic pulmonary disease is often associated with some degree of *atrophy of the entire heart,* so that relative hypertrophy of the right ventricle is frequently overlooked. With the employment of techniques in which a ratio of left/right ventricular weight, or of left ventricular and septum/right ventricular weight, is obtained, a higher necropsy incidence of chronic cor pulmonale is being reported (Thomas, 1951; Fulton et al., 1952; Wells, 1954b). There will probably be a great increase in the future incidence of chronic cor pulmonale, mainly because better therapy has permitted longer survival of patients with chronic pulmonary disease, particularly pulmonary tuberculosis. Healing often results in pulmonary fibrosis.

THE CAUSES OF CHRONIC COR PULMONALE

Chronic cor pulmonale develops when the involvement (structural or functional) of the lungs or its vessels is bilateral and diffuse, and not unilateral or focal. Classifications in the past have usually been based on the anatomic location of the pulmonary disease process More useful is a classification which correlates anatomic and functional abnormalities and, in addition, has important therapeutic implications According to this classification, the etiology of chronic cor pulmonale may be divided into three main groups. type I—pulmonary diseases and dysfunction associated with chronic diffuse obstructive emphysema; type II—pulmonary diseases and dysfunction with chronic alveolar hypoventilation; and type III—pulmonary diseases in which the pathologic process and dysfunction are localized in or about the pulmonary vessels (see Classification of Causes of Chronic Cor Pulmonale) This classification is not rigidly exclusive, for some cases may demonstrate features of more than one type of pulmonary involvement Therapy is usually much more satisfactory in chronic cor pulmonale of types I and II than in type III This is so because at least some of the structural and functional abnormalities which cause the development of chronic cor pulmonale in these types are partially reversible (Mack and Snider, 1953) This reversibility will be regularly noted in the discussion to follow

In patients with chronic pulmonary disease having a markedly restricted pulmonary vascular bed, the abrupt development of some pulmonary catastrophe, such as extensive pneumonitis or massive collapse of a lung, which produces a critical increase in pulmonary vascular resistance, may cause a rapid dilatation of the right ventricle associated with myocardial ischemia and death The clinical picture, the electrocardiographic changes, and the pathologic findings will be similar to those of acute cor pulmonale, although no pulmonary embolization has occurred (Mack et al., 1950).

IV Combinations of types I through III

TYPE I: PULMONARY DISEASE WITH PREDOMINANT CHRONIC DIFFUSE OBSTRUCTIVE EMPHYSEMA

In the United States, chronic diffuse obstructive emphysema is by far the commonest cause of chronic cor pulmonale. While there is considerable controversy about the pathogenesis of this process, there is little argument about the functional abnormalities

Chronic diffuse obstructive emphysema is associated with an absolute increase in the residual volume and functional residual capacity There is a decrease in the vital capacity and maximum breathing capacity, the decrease of the latter being more marked. The work of breathing is greatly increased (McIlroy and

Christie, 1954). The larger functional residual capacity, coupled with a widespread but irregular loss of pulmonary elasticity and bronchiolar obstruction, results in a marked impairment of the distribution of inspired air to mixed venous blood (defective intrapulmonary mixing). As the disease progresses, hyperventilation may cause a decrease of the partial pressure of carbon dioxide in arterial blood during exercise without significant hypoxemia. At a later stage, especially with superimposed infection, *hypoxemia* occurs. Eventually, hyperventilation becomes inadequate and *hypercapnia* results. Finally, the respiratory center becomes insensitive to carbon dioxide. Under these circumstances, the main stimulus to respiration is hypoxemia acting on the aortic and carotid chemoreceptors (Baldwin et al, 1949).

Chronic Bronchitis and the Idiopathic Types of Chronic Obstructive Emphysema. In most cases, chronic bronchitis, sometimes but not always associated with bronchiectasis, appears to be the main cause of this type of emphysema (Baldwin et al., 1949, Spain and Kaufman, 1953; Donald, 1953) Most patients with chronic diffuse obstructive emphysema of the so-called idiopathic type thus give a history of repeated lower respiratory tract infections, with chronic cough and expectoration of many years' duration In such cases, it is quite certain that the chronic bronchial and bronchiolar infection with obstruction has been primary in the genesis of the disease, the loss of pulmonary elasticity being secondary Occasionally, however, patients with diffuse obstructive emphysema are encountered in whom such a sequence has not occurred In such instances, the clinical and functional picture of chronic diffuse obstructive emphysema develops rather suddenly, without a long history of chronic cough. There is evidence that in these patients, some poorly understood degeneration of the pulmonary elastic tissue precedes the diffuse airway obstruction It has been suggested that this represents a *degenerative disease of the elastic tissue of the lung*, possibly secondary to obliterative disease of the bronchial arteries (Cudkowicz and Armstrong, 1953; Lilienthal and Riley, 1954). Once the elastic tissue has become disrupted, bronchiolar obstruction does occur on expiration, bronchial cleansing is impaired, and eventually the picture of chronic bronchial infection becomes manifest. Thus, the end stages of these two quite dissimilar pathogenetic mechanisms become almost identical. At present, the implications for treatment are identical, regardless of the origin of the process, since therapy is mainly directed against the diffuse airway obstruction and infection Chronic diffuse obstructive emphysema occurs more frequently in males, in industrial urban centers, particularly in the North Temperate regions, and in mining regions There is no complete agreement that it is more common among those who do heavy labor and among heavy smokers; some feel that atmospheric pollution is more important (Fulton, 1953, Flint, 1954; Lowell et al, 1956).

Bronchial Asthma. Bronchial asthma produces chronic cor pulmonale only if it is severe, of long standing, associated with recurrent infectious bronchitis, and has led to the development of severe diffuse obstructive emphysema. Acute transitory pulmonary arterial hypertension has been demonstrated by cardiac catheterization during *status asthmaticus*

Chronic Pulmonary Tuberculosis. Chronic cor pulmonale develops in chronic pulmonary tuberculosis, usually when there is a complicating severe diffuse obstructive emphysema In such cases, the diffuse obstructive emphysema is a consequence of healed endobronchial tuberculosis and recurrent nonspecific chronic bronchitis and bronchiolitis. Further compromise of ventilatory function and pulmonary circulation often results from extensive destruction or distortion of pulmonary parenchyma; this occurs with scarring, permanent collapse therapy, extensive pleural fibrosis, extirpative surgery, and massive pulmonary artery thrombosis

Sarcoidosis. Sarcoidosis causes chronic cor pulmonale only when the pulmonary involvement is diffuse and severe. This involvement may be of two types In the first type, the granulomatous infiltration is predominantly *peribronchiolar and endobronchial*, resulting in diffuse bronchiolar obstruction and severe diffuse obstructive emphysema. In the second type, the granulomas are located predominantly *interstitially* compressing arterioles, and *in the interalveolar septa* compressing the capillaries, as well as thickening the alveolar capillary membrane (Austrian et al., 1951) This latter type will be discussed in greater detail in the third large category of the causes of chronic

cor pulmonale In most cases of diffuse pulmonary sarcoidosis, both types of changes are present, however, not infrequently, one or the other type of involvement predominates Chronic diffuse emphysema in sarcoidosis has two distinct features not observed in the common obstructive type of emphysema. (1) a greater degree of hyperventilation, which sometimes minimizes the effect of poor gas distribution upon the index of interpulmonary mixing, (2) a lesser disturbance of intrapulmonary gas mixing (Coates and Comroe, 1951; Mc Clement et al, 1951) Diffuse pulmonary *sarcoidosis*, like all diffuse infiltrative processes in the lung, often goes on to the development of multiple small cystic areas and bullae (*honeycomb lung*), and is frequently complicated by spontaneous pneumothorax Pleural complications resulting from this development may further impair pulmonary function, if indeed the pneumothorax does not cause acute cor pulmonale and death (Mack et al., 1950) Sarcoid infiltration of the myocardium may be present, and may cause AV block and sudden death A left heart "strain" pattern has been reported in myocardial *sarcoidosis* (Peacock et al, 1957). Where *sarcoid* involves mainly the hilar nodes, chronic cor pulmonale does not develop However, even in such cases, considerable parenchymal infiltration may be present, the roentgenogram often being deceptively clear

Kyphoscoliosis. Chronic cor pulmonale frequently develops in severe kyphoscoliosis. While the major abnormality is *alveolar hypoventilation* due to anatomic restriction of the chest bellows (to be amplified below), these patients suffer from *recurrent bronchopulmonary infections*, which are often perpetuated by interference with bronchial cleansing and a poor tussive mechanism In such cases, diffuse airway obstruction, defective intrapulmonary mixing, and all the functional and structural abnormalities of obstructive emphysema combine with the restriction of the chest bellows to lead to chronic cor pulmonale (Mack and Snider, 1956, Gray, 1956, Snider et al, 1958)

Pneumonoconiosis Many of the pneumonoconioses may be associated with severe diffuse obstructive emphysema, and chronic cor pulmonale may result This includes silicosis, coal miners' pneumonoconiosis (anthrosilicosis), bauxite pneumonoconiosis (Shaver's disease), and diatomite pneumonoconiosis (Vorwald, 1957).

Fibrocystic Disease of the Pancreas. In fibrocystic disease of the pancreas (mucoviscidosis), the production of an abnormal viscid secretion in the bronchial glands leads to diffuse bronchial and bronchiolar obstruction and recurrent bronchopulmonary infection Diffuse obstructive emphysema develops, and chronic cor pulmonale is a frequent finding in advanced cases (di Sant' Agnese).

Pathologic Physiology of Type I Chronic Cor Pulmonale. Hypertrophy of the right ventricle develops in chronic diffuse obstructive emphysema because of its increased work. The reversibility of those elements which cause the right heart strain will be *stressed, since when* therapy is attempted, it is this very *element* of *reversibility* which offers hope of improvement (Mack and Snider, 1956). This increased load on the right ventricle is a result of increased resistance to pulmonary blood flow and, when present, of increased cardiac output.

INCREASED RESISTANCE TO PULMONARY BLOOD FLOW Increased resistance to the flow of blood through the lungs in chronic obstructive emphysema results from (1) a *reduction in* the cross-sectional diameter and the distensibility of the pulmonary vascular bed; (2) increased viscosity of the blood (if polycythemia has developed), and (3) possibly certain functional consequences of an expansion of intrapulmonary vascular shunts

Reduction in Cross-sectional Diameter and Distensibility of the Pulmonary Vascular Bed. The evolution of the complicated circulatory system present in higher vertebrates, by producing a complete division of the primitive ventricle into two chambers, not only resulted in the separation of arterial from venous blood but also provided conditions in which the systemic pressure could be raised without directly affecting the pulmonary blood pressure and blood flow Thus, in man, as well as in all higher vertebrates, while the systemic arterial circulation is a high-pressure system, the pulmonary circulation operates under low pressure with a low resistance to blood flow. This low resistance is a result of the large caliber and the marked distensibility of the pulmonary vascular bed The pulmonary capillaries lack tissue support and are exposed over nearly their entire surface to their environment. The fact that only a small increment in pressure occurs with a greatly increased volume of blood flow is of great

adaptive significance, since a markedly increased pressure in such a capillary bed would produce a transudate and would disturb respiratory function (Rodbard et al., 1949; Rodbard, 1953). In normal man in the upright position, pressure in the pulmonary artery remains unchanged, even when the cardiac output is doubled (Hickman and Cargill, 1948). Even with severe exercise, only slight increases in pressure in the pulmonary artery occur (Freedman et al., 1955). Thus, pulmonary blood flow may increase markedly with only an increase in the velocity of flow and in the caliber of the pulmonary vascular bed, but with little or no increase in pulmonary artery pressure. This enlargement of the pulmonary vascular bed results not only from the distention of the individual vessels but also from the opening of vessels formerly not functioning for flow The distensibility of the pulmonary vascular bed may be lowered by a reduction in the total number of vessels in the lung (since each vessel contributes its increment of distention), by a reduction in caliber of the vessels, and by an increase in rigidity of the individual vessel walls (Mack and Snider, 1956)

Contributing to the reduction in cross-sectional diameter and distensibility of the pulmonary vascular bed in chronic obstructive emphysema are the following pathologic changes·

1. *Conversion of many small air spaces into fewer larger air spaces and bullae* by the rupture of interalveolar septa involves a true loss of capillary bed. In addition, many of the vessels adjacent to the bullae are compressed. Because of the dependence of air entrapment on bronchial and bronchiolar obstruction, treatment may reduce the size of bullae.

2. *Shrinkage of the vascular bed in the lungs* occurs also in areas of necrosis with replacement by relatively avascular scar tissue, which is frequently supplied by blood from the bronchial rather than the pulmonary arteries.

3 *Vascular narrowing and diminished distensibility* may also result from the following Actual compression of the capillary bed occurs in the scattered areas of alveolar exudate, atelectasis, and entrapment of air, this is reversible Periarteriolar inflammatory exudate and fibrosis will also produce narrowing. Actual thrombosis develops in many of the capillaries, arterioles, and small pulmonary arteries. Resolution and recanalization may partially reverse these changes Vascular changes secondary to increased intravascular pressure also contribute to the reduction in the vascular bed. They include endarteritis obliterans, medial hypertrophy, pulmonary atherosclerosis, and occasionally necrotizing arteriolitis. These changes increase resistance to blood flow and, hence, pulmonary vascular pressure, the latter furthers the secondary hypertensive vascular morphologic changes. A vicious cycle thus becomes established. Changes in the small vessels are more important than atheromatous changes in the pulmonary arteries, unless the latter lead to thrombosis. It is known from studies in other conditions, in which secondary pulmonary vascular changes occur, such as mitral stenosis and some types of congenital heart disease associated with pulmonary hypertension, that many of these secondary vascular changes (particularly the endarteritis obliterans and the medial hypertrophy) are partially reversible.

4. *Hypoxia produces pulmonary hypertension* (Euler and Liljestrand, 1946), but how it effects this is still a subject of considerable controversy. There is disagreement as to the degree to which the pulmonary circulation reacts passively to changes in cardiac output and shifts in blood volume from the systemic to the pulmonary circulation, and the extent of local and neurohumoral mechanisms which actively alter the resistance to flow and thus control, in some degree, the flow through the pulmonary vascular bed (Lilienthal and Riley, 1954). Some observers have felt that the pulmonary arterioles are not capable of much constriction. However, Burton (1958) has shown that the pulmonary arterioles are capable of contraction He produced casts of the pulmonary arterioles after the administration of rather large amounts of norepinephrine, and demonstrated marked "gnarling" of these vessels, owing to contraction of the helical muscles. Moreover, indirect measurements of the vascular resistance of the lungs based on pressure and flow are often complicated by passive changes in resistance induced by alterations in pulmonary blood flow (Doyle et al, 1952, Williams, 1954, Aviado and Schmidt, 1955) It is agreed that hypoxia causes an increase in cardiac output, which, in the face of an already restricted pulmonary vascular bed, contributes significantly to the pulmonary hypertension However, whether or not hypoxia causes an increase in resistance to blood flow through the lungs is still very much in dispute The subject is further complicated by the fact that various observers have studied this phenomenon in different species of animals under widely varying experimental conditions, and after the production of varying degrees of hypoxia *However, a vast body of convincing experimental evidence indicates that there are local as well as neurohumoral mechanisms which, in response to hypoxia, increase pulmonary resistance by an actual reduction in the caliber of the pulmonary vessels* The site of this vasoconstriction is as yet unknown, various investigators having placed it in the pulmonary arterioles, capillaries, or venules (Nisell, 1950, Hall, 1953, Duke, 1954, Cournand, 1957). Some

mechanism must exist to account for the absence of significant venous admixture appearing in arterial blood during periods of minimal ventilation in normal man, and in diseased states, when ventilation is reduced or abolished in certain areas of the lungs (Lilienthal and Riley, 1954) When chronic hypoxia has led to polycythemia, additional factors increasing resistance to pulmonary blood flow are brought into play and are discussed below. Hypoxia and its effects are reversible.

5 While there has been suggestive experimental evidence that hypercapnia also contributes to an increase in pulmonary arterial pressure, the extent and the mechanism of this effect are as yet imperfectly understood (Nisell, 1950, Shepard, 1954, Lilienthal and Riley, 1954).

Secondary Polycythemia. Secondary polycythemia in chronic obstructive emphysema is caused by hypoxemia. *Hypoxemia stimulates erythropoiesis,* not by a direct effect on the bone marrow, but by increasing the production of a plasma erythropoietic stimulating factor (*erythropoietin*) The site of erythropoietin elaboration is as yet unknown (Erslev, 1953; Stohlman et al, 1954, Reissman, 1955). Secondary pulmonary polycythemia is not associated with marked leucocytosis and thrombocytosis, as is polycythemia vera.

Secondary polycythemia is not invariably present, even in the presence of marked arterial oxygen desaturation It has been suggested that chronic bronchopulmonary infection may be one of the factors causing such failure of the hematopoietic response (Wilson et al, 1951) *Secondary polycythemia is associated with an increased blood viscosity and an increased blood volume, due to an increased red cell mass* The increased viscosity increases the resistance to blood flow in the lungs, but to what extent is unknown Van Liere has shown that an increase of one-third in the proportion of red cells increases the viscosity of the blood three times. However, the viscosimeter measures blood as though it were a homogeneous fluid There is probably an axial flow of red cells in the small arterioles while the plasma moves slowly along the periphery (Brinton, 1951) The effect of viscosity will probably be most marked when the blood flow is at a slow rate and the vessels are reduced in size (Lewis et al., 1952), the conditions prevailing in patients with chronic cor pulmonale and cardiac failure

The increased blood volume in secondary polycythemia is due almost entirely to an increase in red cell mass; *the plasma volume is usually normal,* except in the presence of congestive failure or immediately after recovery from failure. This *hypervolemia* is usually associated with an increased venous return, an increased cardiac output, and probably an increased residual volume of blood in the lung. The latter, in face of an already limited pulmonary vascular capacity, may result in a further encroachment on the ability of the pulmonary vascular bed to accommodate an increased blood flow without an increase in pressure. Increased residual blood in the lungs also decreases pulmonary compliance (Mack et al, 1947), and so would tend to increase the work of breathing. Since satisfactory methods are not available for determining pulmonary residual blood volume, the importance of this factor cannot be evaluated.

Secondary polycythemia in patients with chronic obstructive emphysema is an attempt at compensation, not only because the polycythemia causes an increase in the oxygen capacity of the arterial blood, but because the hypervolemia, by increasing venous return to the heart, helps to increase cardiac output and maintain a high pulmonary blood flow (Guyton et al, 1954, Mack and Snider, 1956). Such indeed occurs in normal people exposed to high altitudes, where the adjustment to hypoxemia includes polycythemia, and often also, increased cardiac output. Some fear that bleeding a polycythemic subject with chronic lung disease may uncover a state of oxygen unsaturation, reflecting the conditions which originally led to the development of the secondary polycythemia (Lewis et al., 1952). However, in a patient with chronic obstructive emphysema, at some point, the deleterious effects of the polycythemia probably outweigh the possible advantages because of the restricted pulmonary vascular bed. Furthermore, Starling demonstrated that a rising filling pressure (venous or right atrial pressure) caused an increase in cardiac output only through a limited range If the filling pressure were increased beyond a certain value, the output would reach a plateau, and if the pressure were raised further (overdistention of heart), the output would begin to decrease Thus, Mc Michael observed that in some patients with chronic cor pulmonale, the cardi-

put usually "fell" on the "normal," or left, side of Starling's curve, so that lowering of venous pressure by venesection led to a decrease in cardiac output. The immediate effect of bleeding in such a case would be undesirable. However, others have studied cases of chronic cor pulmonale in severe congestive failure, when the venous pressure was very high, when cyanosis was extreme, and where the state of the patient's heart "fell" on the right side of Starling's curve (i e, the right ventricle was overdistended). In such cases, phlebotomy (which decreased the venous pressure) remedied the overdistention of the heart, increased cardiac output, and improved the blood flow to the tissues of the body (De Vries et al., 1950) It is possible that in the future, the exact extent to which phlebotomy should be employed in therapy will be determined from correlative studies of viscosity, pulmonary vascular resistance, pulmonary residual blood, total blood volume, and cardiac output. Phlebotomy should be utilized moderately in therapy and only in conjunction with all the other therapeutic procedures available to treat the pulmonary disease

Intrapulmonary Vascular Shunts. While there is no complete agreement about the extent or even the existence of precapillary anastomoses between the bronchial arteries and the pulmonary arteries in the normal lung (Liebow et al., 1949; Tobin and Zariquiey, 1953), their presence and considerable size have been clearly demonstrated in diseased lungs (Liebow et al, 1949). In dogs, following ligation of one pulmonary artery, collateral circulation from the bronchial arteries will expand to such an extent that one-third of the cardiac output will be carried by the bronchial arteries on that side (Bloomer et al, 1949) (see also Chap. 3)

Large and numerous precapillary shunts between the bronchial and pulmonary arteries have been demonstrated in lungs with chronic bronchial infection, tuberculosis, and chronic fibrosing disease by Liebow and associates. They feel that the expansion of these anastomoses in chronic obstructive emphysema is related to their development or enlargement in granulation tissue, in areas of organizing pneumonitis, in the walls of bronchiectatic sacs, and in areas of lymphoid hyperplasia and hypertrophied bronchial smooth muscle They suggest the following consequences of such functioning anastomoses between a high- and low-pressure system. (1) They might act to shunt desaturated pulmonary artery blood away from poorly ventilated areas of the lung, in which they occur to the greatest extent, thus, whatever blood does pass through these poorly ventilated areas would have a higher oxygen content, and less pollution of the systemic blood would then occur (2) They increase the blood flow through the lungs, and in the presence of a restricted vascular bed serve to further elevate pulmonary artery pressure. (3) They tend to increase the work of the left ventricle, since in effect they are a shunt between the left ventricle and left atrium. (4) They may produce an actual reversal of blood flow in the pulmonary artery toward the hilus in some areas; catheterization of patients with extensive bronchiectasis limited to one lung has been shown to yield blood from the pulmonary artery on the affected side that was almost arterial in character (Roosenburg and Deenstra, 1954).

The existence of *anastomoses between the bronchopulmonary veins and the pulmonary veins* has long been recognized (Zuckerkandl, 1882) (see also Chap. 3). The smaller bronchi are drained by the pulmonary veins, while the bronchopulmonary veins drained the proximal two to three orders of branches of the trachea and surrounding interstitial tissue. The bronchopulmonary veins drain into the azygos and hemiazygos systems, the pulmonary veins into the left atrium Normally, blood flow across these anastomotic channels is from the pulmonary veins to the bronchopulmonary veins and thence to the azygos or hemiazygos veins. This is so because the pressure in the left atrium is higher than in the right and because there are valves at the site of entrance of the bronchopulmonary veins into the azygos and hemiazygos veins which ensure unidirectional flow The value of these anastomoses is seen where suppuration exists in the lungs, causing thrombosis of pulmonary veins. In such cases, blood is drained away from the area by the bronchopulmonary veins (Liebow, 1953).

In chronic obstructive emphysema, great expansion in the extent and size of these anastomotic venous channels has been demonstrated. The causes of this expansion are incompletely understood Liebow has suggested that changes in the respiratory pumping action in chronic obstructive emphysema, which affect the true pulmonary venules to a greater extent than the more protected bronchopulmonary venules, might favor this expansion Bullae have been shown to represent expanded parts of the respiratory tract more proximal than alveoli, and the venous drainage of these structures is by way of the bronchopulmonary veins rather than by the pulmonary veins, just as their arterial supply comes from the bronchial arteries. Also, it has been shown that the

walls of bullae contain granulation tissue and much smooth muscle. During the formation of granulation tissue, these anastomotic channels form and persist, even after resolution or cicatrization

In chronic obstructive emphysema, an actual reversal of flow in these expanded channels may occur, so that blood would flow from the bronchopulmonary veins to the pulmonary veins. This might occur, particularly in chronic cor pulmonale with right heart failure, where the pressure in the azygos-hemiazygos system will exceed that in the pulmonary veins In addition, dilatation of the bronchopulmonary veins will cause the stretching of the valve rings at their connections with the azygos or hemiazygos veins, producing incompetence of these valves Such reversal of blood flow would tend to cause pollution of systemic arterial blood by desaturated hypercapnic venous blood, and could thus furnish an important proportion of the venous admixture in the arterial blood

This expansion of the bronchial arterial and bronchopulmonary venous systems, clearly demonstrated in chronic obstructive emphysema, has been quantitatively evaluated (see Chap 3) Evidence for their existence should stimulate the development of methods for assessment during exercise and during respiratory infections

The presence of *precapillary anastomoses* between pulmonary arteries and pulmonary veins has been demonstrated in normal man, but it is apparently not extensive enough to be significant under ordinary circumstances (Tobin and Zariquiey, 1950)

Perfusion of poorly ventilated parts of the lung is equivalent in effect to shunting blood from the pulmonary arterial to the pulmonary venous system However, in chronic pulmonary disease, this phenomenon is minimized (Wilson et al, 1951), since blood flow through these areas usually is reduced markedly by all the mechanisms described as causing an increased resistance to blood flow

CARDIAC OUTPUT. The divergence in the reported studies of cardiac output in chronic cor pulmonale due to chronic obstructive emphysema (Dexter et al, 1951, Harvey et al, 1951, Taquini and Gonzalez, 1951, Fowler et al, 1952, Whitaker, 1954) is explained by the fact that the cardiac output at any particular time in these patients depends on a complex interplay of many variables—not only on the type and extent of pulmonary disease present, but also on the stage of the disease in which the patient is being studied—and will be profoundly affected by the presence of acute bronchitis or pneumonitis, the degree of hypoxia, the severity of polycythemia, the blood volume, and, very importantly, the presence and degree of heart failure.

An increased cardiac output, especially in the face of heightened pulmonary vascular resistance, greatly increases the work of the right ventricle. The following mechanisms act to increase cardiac output in chronic cor pulmonale. Exercise increases cardiac output; even a mild increase in cardiac output through a restricted pulmonary vascular bed causes a disproportionate increase in work of the right ventricle. *Hypoxia acts directly to increase cardiac output If polycythemia is present, the associated hypervolemia will also contribute to an increased cardiac output.* Activity of the inflammatory process in the lung, since some degree of bronchopulmonary infection is always present even in the absence of fever, tends to increase oxygen consumption of the body and thereby lead to an increase in cardiac output. The increased muscular work of breathing, shown to be present in chronic obstructive emphysema, also disposes to an increased cardiac output (Mc Ilroy and Christie, 1954; Otis, 1954) Should cardiac failure occur at a stage when the cardiac output is elevated, some drop in cardiac output will occur, but the output may still be higher than normal The paradox of "high-output failure" is thus explained by the magnitude of the output just preceding failure of the right ventricle (Harvey et al, 1951, Katz, 1954).

When congestive heart failure develops, the increased plasma volume which so often accompanies congestive failure also helps to maintain the cardiac output (Guyton et al, 1954, Starling, 1918), however, later, by contributing to the overdistention of the right ventricle, it may help to lower it.

All these factors which act to increase cardiac output are potentially reversible by intense treatment; a patient who has a high cardiac output during a desperate stage of his illness may have a normal output after a successful course of treatment. If the above factors, which tend to produce an increased cardiac output, are less marked in extent or of shorter duration, a normal cardiac output may be observed

A *lower-than-normal cardiac output* may appear in chronic cor pulmonale due to chronic obstructive emphysema under various circum-

stances. Most important is the effect of severe cardiac failure in causing a marked lowering of cardiac output. If the factors tending to produce high cardiac output are present but pulmonary vascular resistance is high (over four times normal), cardiac output will be low (Dexter et al., 1951). In such instances, the markedly restricted vascular bed of the lung acts very much like a "tight mitral stenosis" in limiting pulmonary blood flow and hence cardiac output. This marked increase in pulmonary vascular resistance may be due to the severe anatomic changes in the lungs associated with the chronic obstructive emphysema, as described above, or it may be due to a coexisting disease, such as multiple pulmonary emboli (Harvey et al., 1951).

In chronic cor pulmonale with congestive failure, the administration of *digoxin* intravenously may cause a paradoxical rise in pulmonary artery pressure. This can be explained by the fact that digoxin causes an increase in cardiac output and probably better emptying of the failing right ventricle. The resultant increased blood flow through a pulmonary vascular bed which is reduced in size and in distensibility causes a rise in pulmonary artery pressure. Acute digitalization in patients with cardiac failure with chronic pulmonary disease and pulmonary hypertension, but with arteriosclerotic or hypertensive heart disease, causes a drop in pulmonary artery pressure This, thus, differentiates pulmonary hypertension due to a reduction in the pulmonary vascular bed from that due to left ventricular failure (Ferrer et al., 1950)

While these patients have pulmonary arterial hypertension, their pulmonary arterial wedge pressure is normal This differentiates the pulmonary hypertension present in chronic obstructive emphysema from that which may be present in patients with mitral stenosis or left ventricular failure, where both the pulmonary arterial wedge and the pulmonary arterial pressures are elevated (Dexter et al, 1951). Often, in a patient with chronic cor pulmonale in congestive failure with marked pulmonary hypertension and increased cardiac output, repeat catheterization after intense pulmonary and cardiac therapy will show the cardiac output to be normal, and the pulmonary artery pressures normal or nearly normal at rest, becoming elevated only with exercise (Harvey et al., 1951).

Since intensive treatment of bronchopulmonary disease increases the size of the pulmonary vascular bed, as well as reducing or abolishing hypoxia with its circulatory effects, it is difficult in any specific case to know which abnormality is responsible for the precipitation of right heart failure. While some observers feel that hypoxia is the main culprit, it is quite likely that the relative importance of each factor varies from case to case, and that, in some cases, therapy is effective mainly because it actually reduces the extent of anatomic restriction of the pulmonary vascular bed by partially reversing the pathologic processes described above (Mack and Snider, 1956).

TYPE II: CHRONIC ALVEOLAR HYPOVENTILATION SYNDROMES

This category includes disorders in which the important functional abnormality is *alveolar hypoventilation*, which, when of sufficient severity and duration, leads to hypoxemia, hypercapnia, polycythemia, pulmonary hypertension, right ventricular hypertrophy, and failure. This category may be subdivided into two groupings: (1) conditions associated with poor functioning of the chest bellows, and (2) primary disease (insensitivity) of the respiratory center (see classification, Causes of Chronic Cor Pulmonale, above). In most of the chronic alveolar hypoventilation syndromes, the respiratory center becomes less sensitive to the carbon dioxide stimulus because of the chronic hypercapnia Further carbon dioxide retention may contribute to a vicious cycle by further depressing respiration and interfering with carbon dioxide excretion (Auchincloss et al, 1955). This loss of sensitivity to the carbon dioxide stimulus is reversed by weight reduction in the cardiopulmonary syndrome associated with obesity. Whether or not it is reversible in the other conditions, is not known, but it is known that it is not reversible in chronic diffuse obstructive emphysema (Baldwin et al, 1955)

Defective Chest Bellows. MASSIVE BILATERAL PLEURAL THICKENING. Encasement of both lungs by a markedly thickened inelastic pleura may restrict the bellows action sufficiently to cause severe alveolar hypoventilation. In some

cases, the chest bellows is further impaired by paralysis of a hemidiaphragm, resulting from a phrenic crush that occurred in the past At necropsy, these patients show no intrinsic disease of the pulmonary parenchyma or of the pulmonary vessels (Feltman et al., 1952, Cabot, Case 43421; Coates et al , 1958).

CHRONIC NEUROMUSCULAR DISORDERS Defective action of the chest bellows due to chronic neuromuscular disorders has been reported to cause chronic cor pulmonale. This has been observed in patients with severe residual respiratory paralysis after poliomyelitis, muscular dystrophies, myasthenia gravis, or amyotrophic lateral sclerosis After poliomyelitis, a primary involvement of the respiratory center by this syndrome is possible, but the part played by this factor is not always easy to evaluate The exact effect of prolonged *existence in a respirator* has also yet to be fully assessed (Lucas and Plum, 1952, Blossom and Affeldt, 1956, Cherniack et al , 1957; Eldridge, 1958)

KYPHOSCOLIOSIS In severe kyphoscoliosis, the development of pulmonary insufficiency and chronic cor pulmonale has been long recognized Only recently, however, have detailed *pulmonary function tests* (measurement of lung volumes, airway obstruction, distribution defect, and diffusion capacity) as well as studies of altered cardiovascular dynamics (right heart catheterization) been available.

In severe kyphoscoliosis, there is restriction of the chest bellows with ventilatory dysfunction reduced lung volumes, lowered vital capacity, and lowered maximum breathing capacity There is an increase in the work and energy cost of breathing, to which a partial adjustment is made by a breathing pattern of small tidal volume and a rapid respiratory rate (Grav, 1956, Fishman et al , 1958) This type of breathing pattern involves a relative increase in dead-space ventilation, at the cost of alveolar ventilation When alveolar hypoventilation is severe enough, *hypoxemia* (with all its unfavorable consequences, described below) and *hypercapnia* develop

There is disagreement among observers as to the presence of other functional abnormalities in these patients. Some feel that the cardiopulmonary abnormalities are due exclusively to *alveolar hypoventilation* resulting from restriction of the chest bellows, with consequent hypoxemia and hypercapnia. The chain of events (hypoxemia, hypercapnia, polycythemia, pulmonary hypertension, and chronic cor pulmonale) is considered to arise mainly as a result of this alveolar hypoventilation (Schaub et al , 1954). Others feel that an *anatomically restricted vascular bed* also contributes to the increased load on the right ventricle, since pulmonary hypertension may be observed in some patients with exercise in the absence of arterial hypoxemia (Fishman et al., 1958). Angiocardiographic studies have shown that no significant kinking of the pulmonary artery occurs.

Some observers feel that airway obstruction, defects in intrapulmonary mixing, and obstructive emphysema are not usually present in kyphoscoliotic patients who have developed chronic cor pulmonale (Fishman et al., 1958). However, other observers and the author have seen and reported cases where diffuse airway obstruction, defects in distribution, and functional and pathologic evidence of diffuse obstructive emphysema were apparent (Fischer and Dolehide, 1954, Mack and Snider, 1956; Gray, 1956).

It is most striking that respiratory and cardiac insufficiency are usually *not present early in life*, but develop only after the passage of time It is during this significant time interval that these patients suffer from acute and chronic, recurrent and lingering bronchopulmonary infections, probably associated with *diffuse bronchiolar obstruction* These infections are perpetuated by interference with [illegible] mecha- [illegible] the re- [illegible] the chest bellows Destructive changes in the lung, with areas of emphysema and *atelectasis*, then become superimposed on the impaired respiratory mechanics Chronic obstructive emphysema thus gradually develops, and the restricted vascular bed plus the usual consequences of alveolar hypoventilation combine with it to *produce chronic cor pulmonale* Most of the kyphoscoliotic patients who develop respiratory insufficiency [illegible]

While some patients with severe kyphoscoliosis develop severe cardiopulmonary insufficiency, others, who superficially appear just as deformed, show very little impairment of function or even reduction in life expectancy. There is a great need for some method for (1) evaluating quantitatively the type and severity of the thoracic and spinal deformities, and (2) relating these to total as well as regional ventilatory function, cough efficiency, and pulmonary vascular capacity. Serial observations over a period of time, as a kyphoscoliotic child grows into adulthood, would also be valuable Certainly studies of cardiopulmonary function in children with kyphoscoliosis should not be confused with similar studies in adults, in whom stabilization has occurred, and in whom repeated bronchopulmonary infections may have caused important permanent alterations in the lungs. If the kyphoscoliosis is due to poliomyelitis, the contribution of the residual muscular weakness to the impaired respiratory function is difficult to assess.

Until a better way of quantitating the thoracic deformity and evaluating the natural history in kyphoscoliosis is found, the consequences of kyphoscoliosis may be classified as follows.

1. The deformity is severe enough to cause such marked alveolar hypoventilation that the pulmonary hypertension and chronic cor pulmonale result mainly from the severe hypoxemia, hypercapnia, and polycythemia

2. The deformity is of an extent to cause not only alveolar hypoventilation but also anatomic restriction of the pulmonary vascular bed Pulmonary hypertension occurs with exercise as an expected result of an augmented blood flow through an anatomically restricted vascular bed

3. The deformity is severe enough to cause not only alveolar hypoventilation and often anatomic restriction of the pulmonary bed, but also impaired distribution of inspired air and mixed venous blood. Whether this distribution-perfusion disproportion is most marked in the overdistended lung or the compressed lung is not known at present.

4. While the deformity may cause alveolar hypoventilation, it is not severe enough to initiate the cardiopulmonary chain of events as described above. However, because of an impaired bronchial cleansing mechanism, bronchial and bronchiolar infection and obstruction are perpetuated, producing areas of obstructive pneumonitis with gradual deterioration of pulmonary integrity. Such changes would tend to further decrease alveolar ventilation.

Pectus excavatum, or *funnel chest*, is a thoracic deformity which only very rarely is associated with cardiac or pulmonary dysfunction. However, instances of severe pectus excavatum with heart failure, arrhythmias (especially atrial fibrillation), and catheterization findings demonstrating a pattern of right ventricular pressure similar to that in constrictive pericarditis, have been reported (Ravitch, 1951; Lyons et al., 1955; Wachtel et al, 1956) (see also Part 16, Chap. 12). In most instances, pectus excavatum becomes important because of the psychologic effect of its appearance and because of the abnormalities in the cardiac silhouette which often result in a mistaken diagnosis of heart disease. The heart is shifted to the left, the left middle salient is often prominent, and the transverse diameter of the heart may appear to be enlarged. A systolic murmur often may be heard over the precordium (Master and Stone, 1949; Edling, 1953).

Pectus carinatum, or *pigeon chest*, usually does not cause significant cardiac or pulmonary abnormalities The deformities of the chest produced by *thoracoplasty* do not lead by themselves to chronic cor pulmonale, unless there is extensive disease in the contralateral lung, usually diffuse obstructive emphysema

PICKWICKIAN SYNDROME. There has been an increasing recognition of a syndrome occurring in very obese individuals, which has been called *cardiopulmonary syndrome associated with obesity*, or the Pickwickian syndrome (a term applied by Burwell and associates, because of the startling resemblance of these patients to Mr. Wardle's boy, Joe, in Dickens' *Pickwick Papers*).

The clinical syndrome includes marked obesity, marked somnolence, twitching, shallow respirations, periodic breathing, secondary polycythemia, and chronic cor pulmonale (Sieker et al, 1955, Auchincloss et al, 1955, Burwell et al, 1956, Lillington et al, 1957). These patients suffer from anatomic restriction of the chest bellows as a result of their tremendous obesity. Their work of breathing is increased. The facts that their expiratory reserve volume tends to be low and that their lung approaches the expiratory position

further increase their work of breathing (Butler and Arnott, 1955). They develop a breathing pattern in which total ventilation, respiratory frequency, tidal volume, and alveolar ventilation are abnormally low The alveolar hypoventilation occurs as a result of the reduction in frequency in breathing, as well as the reduction in tidal volume, the latter causing a sacrifice of alveolar ventilation to dead-space ventilation They develop hypoxemia, hypercapnia, secondary polycythemia, pulmonary hypertension, right heart hypertrophy, and eventually failure. This syndrome appears in patients without intrinsic pulmonary disease Their respiratory centers are frequently unresponsive to the carbon dioxide stimulus, however, after weight loss, the center regains its responsivity. Some of the increased tolerance to carbon dioxide in these patients may be due to the fact that there is marked increase in the work of breathing, and it has been shown that an increased work of breathing greatly reduces the ventilatory response to inhaled carbon dioxide, even in normal persons (Chermack and Snidal, 1956). The entire syndrome appears to be reversible if the patient loses weight There is still some uncertainty as to all the factors involved in the pathogenesis of this syndrome Not all very obese patients demonstrate these abnormalities, it has been the author's observation that patients with this syndrome usually have short squat chests with short necks It is conceivable that these patients may also have some disorder of the central nervous system, possibly involving the hypothalamus and the respiratory center.

Insensitivity of the Respiratory Center. Patients have been described who demonstrate alveolar hypoventilation secondary to a diminished ventilatory drive from a damaged respiratory center They have normal hearts and lungs and normally functioning chest bellows They develop hypoxemia, hypercapnia, secondary polycythemia, right heart hypertrophy, and eventually failure They show an absence of dyspnea at rest and during exercise, in spite of the development of severe hypercapnia and hypoxemia. These patients show a low ventilatory response to exercise and inspired carbon dioxide Their cyanosis is aggravated by exercise but is abolished by hyperventilation or the breathing of high oxygen mixtures Pulmonary arteriovenous fistulas are therefore excluded The nature of the damage to the respiratory center is poorly understood but is considered to be inflammatory in some cases and vascular in others (Newman et al., 1951; Ratto et al , 1955, Pare and Lowenstein, 1956, Richter et al , 1957).

TYPE III: PULMONARY DISEASE WITH PREDOMINANT INVOLVEMENT OF THE VESSELS

This category includes those diseases in which the pathologic processes involve mainly the pulmonary vessels (intraluminal or extraluminal). (See the classification Causes of Chronic Cor Pulmonale, earlier in this chapter.)

Intraluminal Processes. In this category, the great restriction of the pulmonary vascular bed is the main cause of the high pulmonary vascular resistance, pulmonary hypertension, and the development of chronic cor pulmonale. There is usually very little ventilatory dysfunction present. However, the diffusion capacity of the lungs may be reduced by the loss of capillary surface area and by the reduced alveolar-capillary contact time, associated with the increased velocity of blood flow through the greatly narrowed pulmonary vascular bed (Luchsinger et al., 1957). *Cardiac output may be reduced, it cannot rise with exercise, and may even fall.*

This severe limitation of cardiac output is especially striking in *multiple recurrent small pulmonary emboli, thrombosis of the major pulmonary arteries,* and *primary pulmonary hypertension* It is responsible for some of the clinical manifestations seen in these patients. It explains the severe exertional dyspnea and weakness. Stimulation of sensory receptors in the pulmonary arteries by the marked increase in pulmonary artery pressure accompanying exercise may cause tachypnea, adding to the sensation of dyspnea (Aviado and Schmidt, 1955).

Exertional syncope occurs often. Various explanations for this symptom have been suggested (1) A *vasovagal reflex*, caused by impulses arising from the pulmonary arteries (Dressler, 1952, Dresdale, 1951, Aviado and Schmidt, 1955) (see Part 14, Chap 3). (2) A marked fall in coronary blood flow caused by an acute rise in right ventricular pressures (Schafer, 1956). (3) Acute failure of the right ventricle, due to a marked increase of pulmonary artery and right ventricular pressures with exercise The last explanation has been

supported by catheterization studies and is probably correct (Howarth and Lowe, 1953).

Episodic cyanosis frequently is present. Occasionally, such cyanosis is associated with a lowered arterial oxygen saturation, as a result of a right-to-left shunt through a valve-competent foramen ovale. However, peripheral cyanosis occurs often even when the arterial oxygen saturation is normal with a closed foramen ovale, because a high extraction of oxygen, consequent to the reduced cardiac output, leads to a high degree of oxygen unsaturation of the venocapillary blood (Shepard et al., 1957). It is, therefore, not due to arterial hypoxemia. Such peripheral cyanosis is noted whenever the blood flow is small in relation to the oxygen utilization of the tissues.

Precordial pain occurs and is usually associated with *dyspnea*. It is not relieved by nitroglycerin. This type of pain has been described in conditions associated with severe pulmonary hypertension and was named "hypercyanotic pulmonary angina" by Vaquez (1908). An identical type of chest pain occurs in any condition associated with severe pulmonary hypertension, such as mitral stenosis or congenital heart disease with severe pulmonary hypertension. Viar and Harrison believe that the pain is due to distention of the pulmonary artery (see also Chap. 7). Others feel that the pain is due to coronary insufficiency related not only to the severely restricted cardiac output but also to the increase in right ventricular pressures (Dresdale, 1951).

Multiple Recurrent Small Pulmonary Emboli. Multiple, repeated, small pulmonary emboli may be discharged over a long period of time, often without the usual clinical manifestations of pulmonary embolization. They are fed to the lungs from the peripheral veins (leg, pelvic, or prostatic veins) or occasionally from the right chambers of the heart. They may also arise from one or two large emboli which have lodged in a major pulmonary vessel. These multiple small emboli lead to a marked reduction in the extent of the pulmonary vascular bed, to pulmonary hypertension, and eventually chronic cor pulmonale (Castleman and Bland, 1946; Owen et al., 1953).

At necropsy, emboli in all stages of organization can be found, with changes reflecting the age of the emboli. Some vessels are filled with granulation tissue, some contain small recanalized channels, and, in some, the emboli have become organized in such a way as to resemble kidney glomeruli. With organization or recanalization, many of the vessels demonstrate changes which strongly resemble arteriosclerosis, particularly fibrous intimal thickening (Owen et al., 1953). Sometimes, only the most careful histologic studies will rule out primary arteriolosclerosis. Such cases were often considered in the past to be examples of primary pulmonary hypertension. These changes in the small pulmonary vessels have been reproduced experimentally in laboratory animals by the injection of various substances into the peripheral veins: macerated autogenous and heterogeneous blood clots, amniotic fluid, and bits of filter paper. The organization of these emboli leads to a type of fibrous intimal thickening often indistinguishable microscopically from localized arteriosclerosis (Wartman et al., 1951; Barnard, 1954; O'Neal and Thomas, 1955). In instances of multiple pulmonary emboli, arteriosclerosis, when found, is proximal to the occlusion, indicating that the hypertension was secondary to the occlusion. Atherosclerotic changes in the major pulmonary arteries may also develop. Because the right ventricle is often markedly dilated, many large mural thrombi may develop in the interstices of the trabeculae carneae, from which more emboli are often detached. Old organized emboli may leave as their only remainder thin fibrous bands bridging the lumens of the secondary and tertiary branches of the pulmonary artery (Castleman and Bland, 1946, Owen et al., 1953). Expansion of the circulation from the bronchial arteries occurs, as evidenced by marked thickening of the pleural and subpleural arteries which are derived from the bronchial arteries (Castleman and Bland, 1946). Often small healed pulmonary infarcts can be found also, which may be missed unless many subpleural sections of the lung are examined.

The clinical manifestations of repeated small pulmonary emboli are variable. While there may be evidence in the history of episodes which can be reconstructed as indicating pulmonary embolism, there may be absolutely no history of chest pain, hemoptysis, or recurrent pleural effusion. *Dyspnea* and *persistent cough* are usually prominent symptoms and may be present for as long as 7 years before the appearance of cor pulmonale and congestive failure (Owen et al., 1953). In Owen's study, patients with massive pulmonary artery thrombosis did not present any clinical features to distinguish them from those with emboli only

in the smaller vessels. Sometimes, the x-ray may be of help in that with massive pulmonary thrombosis, often a large bulky pulmonary artery shadow is seen with a rather sharp termination of a major branch. The peripheral arteries appear diminished, particularly in massive thrombosis of the major pulmonary arteries, in multiple, small pulmonary embolizations, the peripheral vascularity of the lung appears normal. In some instances, a foramen ovale, normally functionally closed, may become patent when right ventricular and atrial hypertension occurs. *Paradoxical embolism* then becomes possible. Such paradoxical embolism to the brain may produce focal signs, adding to the clinical picture produced by the disease process itself (Cabot, Case 44071).

The diagnosis of multiple pulmonary embolizations, as opposed to that of primary pulmonary hypertension, may be of some therapeutic significance. Kuida and associates feel that one should not make the clinical diagnosis of primary pulmonary hypertension during life, as it implies therapeutic nihilism. If multiple pulmonary emboli are suspected, every attempt should be made to stop their further appearance by prolonged anticoagulant therapy, or ligation of the appropriate veins.

Thrombosis of Major Pulmonary Arteries. Chronic cor pulmonale may result from massive thrombosis of the *major pulmonary arteries*. It was recognized quite early that such extensive autochthonous thrombosis of the main pulmonary artery or its major branches was associated with such fibrosing pulmonary diseases as extensive pulmonary tuberculosis or severe silicosis, atherosclerosis of pulmonary arteries, thromboangiitis obliterans involving the pulmonary artery (Hausner and Allen, 1940), cardiac failure with pulmonary hypertension, and conditions associated with hypercoagulability of the blood. *Most of the cases* now being recognized are secondary to massive pulmonary emboli (Hanelin and Eyler, 1951, Magidson and Jacobson, 1955, Ring and Bakke 1955). Moreover, the presence of one or more of the disorders which are associated with autochthonous pulmonary artery thrombosis does not always exclude the occurrence of pulmonary embolism, but [illegible]

[illegible] artery

In many instances, it has been difficult to understand the survival of these patients with so much obstruction in the pulmonary circulation. As indicated by Brenner (1935), as much as 75 per cent of the pulmonary cross-sectional diameter must be occluded before the systolic blood pressure falls, and 90 per cent, before death occurs. However, the appearance of the occluded pulmonary artery at necropsy may be misleading: during life, much blood may pass through the involved artery because of the distensibility of the vessel, unless the clot is adherent all around (Ring and Bakke, 1955). A very small lumen may be all that remains sustaining life, the final obliteration of this lumen causing death in many instances. Despite massive thrombosis, there is frequently notable absence of any massive infarction. This is probably related to the well-known expansion of anastomoses between the pulmonary and bronchial arteries, which has been demonstrated experimentally after ligation of the pulmonary arteries (Bloomer et al., 1949). However, infarcts are not uncommon and occasionally develop into *abscesses*. Thrombosis of the pulmonary artery has been reported in intraatrial septal defect, in patients who are in their sixth decade of life. It is conceivable that the presence of the intraatrial septal defect helped to prolong life in these cases, when the pulmonary arteries were occluded (Canada et al., 1953).

Clinically, the syndrome may be difficult to recognize. Often the underlying lesions of the lung or heart dominate the clinical picture. Early in the history, there is frequently, but not always, a picture resembling typical pulmonary embolism, with evidence for the source of the embolism being present. The clinical course may be acute, subacute, or chronic. Right heart hypertrophy and progressive, often intractable, right ventricular failure, are typical. Characteristic also is *dyspnea*, often completely out of proportion to the extent of the existing cardiac or pulmonary disease, and in the face of relatively clear lung fields. Severe *cough* and *retrosternal pain* may also be present. *Cyanosis* is not infrequent, and is often marked. *Syncopal attacks* or periods of *mental confusion* occur frequently. A *high-pitched systolic murmur* is frequently audible over the base (Magidson and Jacobson, 1955; Ring and Bakke, 1955).

The x-ray appearance of *massive* pulmonary artery thrombosis has been well described by Hanelin and Eyler: there is dilatation of the pulmonary artery proximal to the block, often with an abrupt *termination* or sharp *cutoff*,

corresponding to the tapering of the bulky portion of the thrombus. There are enlargement and alteration of the contour of the vessels at the level of the thrombus, which can best be described as unusual "lumpiness" There is a decrease in the size of the vessels distad to the thrombus, causing increased radiolucency of the corresponding area of lung. On fluoroscopy, hilar pulsation may be absent on the involved side. Very commonly involved is the right interlobar artery. Angiocardiography has demonstrated the obstruction well.

The incidence of this condition is probably greater than previously realized. While Magidson and Jacobson stated that massive thrombotic occlusion of the main pulmonary arteries was relatively rare, occurring perhaps once in 5,000 necropsies, in a series quoted by Hollister and Cull, 14 cases occurred in admissions to a 335-bed hospital over a 10-year period.

Sickle-cell Anemia. Repeated vascular thromboses in patients with sickle-cell anemia or sickle thalassemia may cause chronic cor pulmonale (Yater and Hansmann, 1936). In these patients, bouts of pleuritic chest pain or unexplained dyspnea, often considered to be caused by pneumonitis, are frequently *episodes of pulmonary infarction due to pulmonary arterial or arteriolar thrombosis.* Moser and Shea feel that cor pulmonale is most likely to develop in those individuals with (1) severe anemia or sudden lowering of the oxygen-carrying capacity and (2) a high percentage of S-hemoglobin. Favoring vascular thromboses also are such conditions as acidosis and left ventricular failure. Pulmonary arterial hypertension and right ventricular hypertrophy result from the high and fixed pulmonary vascular resistance. Since prolonged survival of even severely sicklemic individuals is becoming more common, more instances of this long-range complication of the sickle state will probably become apparent (Moser and Shea, 1957)

Schistosomiasis. Schistosomiasis is a rather frequent cause of chronic cor pulmonale in Egypt, South Africa, Asia, and Puerto Rico Massive and repeated embolization of the lung by the ova of the parasites, with an inflammatory response about the sequestrated ova, causes an extensive *obliterating endarteritis* (Shaw and Ghareeb, 1938). When the pulmonary infection is due to *Schistosoma mansoni*, hepatosplenomegaly with communications between the portal and systemic venous systems is invariably present; in infections with *Schistosoma hematobium*, the ova can pass directly to the lung. So-called angiomatoid structures have been described as typical for this disease (Shaw and Ghareeb, 1938; Girgis, 1952) Their exact function is as yet poorly understood.

Shaw and Ghareeb consider the angiomatoid structures to result from a growth in size of the blood spaces to cavernous dimensions beyond the confines of the original vessels, because of the loss of the controlling effect of the media of the arteries in which they develop. Others have considered them to be merely dilated anastomotic channels that develop between the pulmonary and bronchial vessels, and in some way an adaptation to the obstruction of the pulmonary circulation Some feel that the angiomatoid structures result from canalization of the occluding tissue by newly formed capillaries. Similar structures have been described in primary pulmonary hypertension (Kuida et al., 1957).

Angiocardiography has demonstrated a peculiar lacework aspect of the pulmonary vessels, as well as a persistence of the contrast medium in the lungs beyond the normal period of time after injection (de Faria et al, 1957). This prolonged retention of the dye in the lungs could well have been a feature of the severe increase in pulmonary vascular resistance, and has also been described in primary pulmonary hypertension.

Primary Pulmonary Hypertension. Chronic cor pulmonale may develop from hypertension in the pulmonary circuit in the absence of disease of the lung. In such cases the hypertension is considered to be primary, idiopathic, or essential (see Chap 7). These patients develop progressive right heart enlargement and right heart failure, and at necropsy show no signs of primary pulmonary disease, most of the advanced cases, however, show extensive changes in the pulmonary arterioles and arteries A considerable number of disseminated thromboses in the smallest pulmonary vessels are seen, but they are less extensive than the sclerotic vascular changes (especially intimal hyperplasia). It is believed that these sclerotic changes are *secondary* to some unknown factor causing an increase in pulmonary arterial pressure (Dresdale et al., 1951; Berthrong and Cochran, 1955; Kuida et al., 1957; Chapman

et al , 1957; Evans et al., 1957). While there has been a tremendous increase in the frequency of reports of this condition based on clinical and catheterization studies, it should be emphasized that a necropsy is an essential part of the final diagnostic procedure, since so many other conditions may simulate it. There have even been considerable variations of the pathologic picture at necropsy, so that it is quite likely that primary pulmonary hypertension *represents* not a homogeneous group but *a similar end-stage picture produced by diverse causes.*

Even after the most careful clinical study, the pulmonary hypertension at necropsy may be found to have been secondary to some structural malformation or disease which was previously unsuspected Recurrent silent pulmonary emboli are almost impossible to exclude from primary pulmonary hypertension by clinical means, and indeed often at necropsy.

Shepard et al. (1957) list the techniques that are necessary to exclude secondary pulmonary hypertension as follows (1) cardiac catheterization, (2) oximetry, (3) indicator dilution techniques, (4) inhalation of gas mixtures of different oxygen content, (5) radial and femoral arterial blood samples, (6) simultaneous recording of pulmonary and systemic arterial pressures, (7) pulmonary arterial wedge pressure To this might be added (8) left heart catheterization to exclude cases of "occult mitral stenosis" (Brachfeld et al., 1958)

Diffuse Pulmonary Vasculitis. Polyarteritis nodosa may cause chronic cor pulmonale if extensive diffuse vascular involvement of the lung is present Patchy pulmonary infarction due to vascular occlusion may complicate the picture Specific involvement of the coronary arteries may lead to myocardial infarction and may contribute to the final picture of cardiac failure In polyarteritis nodosa, the involvement is usually mainly of the medium-sized arteries, with the only extravascular lesions being infarcts secondary to occluded vessels However, there are other types of generalized vasculitis in which the involvement is mainly of smaller vessels (arteries, arterioles, veins, and venules), and in which extravascular lesions in other organs occur (parenchymatous changes in the spleen, focal glomerulonephritis) These conditions may also cause cor pulmonale when the pulmonary vascular involvement is extensive; the course is usually subacute.

Secondary Pulmonary Vascular Sclerosis. Extensive changes in the pulmonary arterioles are known to occur in some cases of mitral stenosis, or congenital heart disease with a marked left-to-right shunt (Parker and Weiss, 1936). It has been assumed that sclerotic changes contribute to the development of pulmonary [illegible]
ventricle [illegible]
plied th [illegible]
plexes, it would be wise to exclude them from the classification, although the mechanism is similar.

Other Causes of Intravascular Occlusions in the Lungs. Chronic cor pulmonale associated with pulmonary arteriosclerosis has been reported to have occurred in a patient with marked hyperglobulinemia, cryoglobulinemia, plasmocytosis, and glomerulitis. Proteinaceous masses occluding the small pulmonary arteries were found, which were considered to represent in vivo flocculation of cryoglobulin (Muirhead et al , 1952).

EXTRALUMINAL PROCESSES

This group includes conditions in which there is extensive granulomatous, fibrous, or neoplastic *infiltration of the interstitial tissue of the lungs.* Such infiltration greatly reduces the size and distensibility of the pulmonary vascular bed. This is the main cause for the development of pulmonary hypertension and chronic cor pulmonale. Characteristic of these conditions, when severe, is also a *reduction in the diffusion capacity of the lungs.* The diffusing capacity of the lungs is determined by the capillary surface area available for diffusion, the time interval allowed for equilibration along the alveolar-capillary membrane, and the character and thickness of the tissues constituting the alveolar-capillary barrier. Thickening of the alveolar-capillary membrane by [illegible]
tiss [illegible]
the [illegible] the capillary blood (Austrian et al , 1951). Carbon dioxide is twenty times as diffusible as oxygen, and its impaired transfer is seldom a problem except in the very late stages There has been a tendency to stress *alveolar-capillary block* to the neglect of the other factors influencing the

corresponding to the tapering of the bulky portion of the thrombus. There are enlargement and alteration of the contour of the vessels at the level of the thrombus, which can best be described as unusual "lumpiness." There is a decrease in the size of the vessels distad to the thrombus, causing increased radiolucency of the corresponding area of lung. On fluoroscopy, hilar pulsation may be absent on the involved side. Very commonly involved is the right interlobar artery. Angiocardiography has demonstrated the obstruction well.

The incidence of this condition is probably greater than previously realized. Proteinaceous masses occluding the small pulmonary arteries were found, which were considered to represent in vivo flocculation of cryoglobulin (Muirhead et al , 1952).

EXTRALUMINAL PROCESSES

This group includes conditions in which there is extensive granulomatous, fibrous or neoplastic *infiltration of the interstitial tissue of the lungs*. Such infiltration greatly reduces the size and distensibility of the pulmonary vascular bed. This is the main cause for the development of pulmonary hypertension and chronic cor pulmonale Characteristic of these conditions, when severe, is also a *reduction in the diffusion capacity of the lungs*. The diffusing capacity of the lungs is determined by the capillary surface area available for diffusion, the time interval allowed for equilibration along the alveolar-capillary membrane, and the character and thickness of the tissues constituting the alveolar-capillary barrier. Thickening of the alveolar-capillary membrane by infiltration with granulomas, edema, fibrous tissue, or cords of neoplastic cells will impede the passage of oxygen into the capillary blood (Austrian et al , 1951). Carbon dioxide is twenty times as diffusible as oxygen, and its impaired transfer is seldom a problem except in the very late stages. There has been a tendency to stress *alveolar-capillary block* to the neglect of the other factors influencing the

diffusing capacity. More recently, however, it has been pointed out that the reduction in diffusion capacity in many of these cases is the result not merely of the thickening of the alveolar-capillary membrane but also of the *increased velocity of blood flow through a greatly narrowed vascular bed with consequent critical reduction in the alveolar-capillary contact time.* In such cases, the contact time between alveolus and blood becomes insufficient to allow equilibration between alveolar and capillary oxygen tensions. The result is a widening of the alveoloarterial oxygen tension gradient, reflected in a desaturation of arterial blood, i e., a diffusion insufficiency (Rossier and Bühlmann, 1954; Luchsinger et al., 1957). The cases in this category also usually demonstrate moderate restrictive ventilatory dysfunction, lowered pulmonary compliance, reduced lung volumes, remarkably little reduction in maximum breathing capacity, and usually little or no abnormality in the distribution of inspired air However, Motley (1958) feels that some of the arterial blood oxygen desaturation on exercise in some of these patients is due to perfusion of blood through nonventilated or poorly ventilated areas These patients often show hyperventilation at rest and during exercise, resulting often in *low carbon dioxide tension* in the arterial blood Early, there is usually a normal arterial blood oxygen saturation at rest with marked reduction after exercise, eventually, resting *hypoxemia* develops, sometimes with *polycythemia*, which will increase the load on the right ventricle, just as it does in chronic diffuse obstructive emphysema (Austrian et al, 1951)

Early in the course of their disease, these patients may have a normal or only slightly elevated pulmonary arterial pressure at rest, developing a marked pulmonary hypertension on exercise This is probably mainly the consequence of the anatomically narrowed pulmonary vascular channels which accommodate an increase in pulmonary flow by a marked increase in pulmonary arterial pressure However, some contribution to the pulmonary hypertension must also be made by the exercise-induced hypoxia Eventually, pulmonary hypertension persists at rest. In the absence of cardiac failure, resting hypoxia, and polycythemia, *cardiac output in these patients is frequently found to be elevated.* It has been postulated that this high output in the absence of continual hypoxia is due to the increased metabolism resulting from the active interstitial inflammation in the lungs (Harvey et al., 1951), and the increased work of breathing, occasioned by the restrictive ventilatory defect While most of these patients die of pulmonary insufficiency, some eventually develop marked arterial oxygen desaturation and right heart failure, at which time *cardiac output is found to be low.* The pulmonary hypertension in these conditions usually cannot be reversed.

Sarcoidosis. The ways in which diffuse pulmonary involvement caused by extensive sarcoidosis may lead to chronic cor pulmonale have already been described In the second type, the granulomas are located predominantly interstitially, compressing arterioles and capillaries, as well as markedly thickening the alveolar-capillary membrane (see above). It should be stressed again that a complicating picture of diffuse obstructive emphysema may also be present, although a relatively "pure" form of alveolar-capillary block may be produced by this type of pulmonary sarcoidosis (Coates and Comroe, 1951; McClement et al, 1953, Stone et al, 1953; Marks et al., 1957).

Beryllium Disease. Beryllium disease with diffuse involvement of the lung may produce pathologic and functional derangements identical to those of sarcoidosis (Austrian et al, 1951, Marks et al., 1957). The term "beryllium disease" is preferable to the terms "pulmonary granulomatosis of beryllium workers" or "berylliosis" because the disease is truly a systemic intoxication, with biochemical abnormalities and involvement of the liver, spleen, kidney, and myocardium, as well as the lung.

The mechanism of disease production is comparable to that of a chemical intoxication, such as in lead poisoning, with changes attributed to hypersensitivity phenomena, rather than to a reaction, as in the pneumonoconioses The term berylliosis is completely misleading, because the disease is not produced by the inhalation of beryl ore. The disease-producing substances include beryllium metal, beryllium oxide, alloys of beryllium with other metals, and acid salts of beryllium While a history of exposure to beryllium, as in certain incriminated industrial operations, is extremely helpful, the diagnosis of beryllium disease can be proved only by discovery through spectrographic or chemical means of beryllium in

tissues which show granulomatous lesions (Hardy, 1956)

Histiocytosis X. Chronic cor pulmonale develops in histiocytosis X (eosinophilic granuloma), where the granulomatous infiltration is diffusely present in the lung. Here too, the granulomatous infiltration is located interstitially, causing marked thickening of the alveolar-capillary membrane, as well as restriction of the pulmonary vascular bed. Eventually, there also occurs obliteration of alveoli, with the formation of small nodules, often coalescing to form larger lesions.

All ages of lesions are simultaneously present. The granuloma is composed of monocytic histiocytes or macrophages, eosinophils, and multinucleated giant cells. There occur an increase in blood vessels, fibroblasts, and eventually necrosis and hemorrhage. Cholesterol appears in the histiocytes, causing a foamy appearance. The lesions may go on to resolution or fibrosis. The serum cholesterol level is normal. There is no blood eosinophilia, nor is there increase in serum globulin (Farinacci et al., 1951, May, 1954; Renzetti et al., 1957, Morton, 1957). End stages of the disease may present the picture of diffuse interstitial fibrosis, or honeycomb lung (polycystic lung). In the latter condition many emphysematous blebs develop, a result of either bronchiolar obstruction or scar retraction (Oswald and Parkinson, 1949). Spontaneous pneumothorax then frequently occurs as a complication.

Eosinophilic granuloma was first recognized in bone by Lichtenstein and Jaffe (1940). The possible relationship of this condition to Hand-Schuller-Christian disease and Letterer-Siwe disease was first pointed out by Farber. Eventually, the combination of skeletal and lung lesions was recognized. Lichtenstein (1953) proposed the term histiocytosis X to describe this category of disorders, the histiocytosis *referring to the essential type of histologic cellular reaction, and X referring* to the need for identification of an etiologic agent. Cases with only pulmonary involvement, and others with both skeletal and lung lesions have been described. The clinical differentiation between eosinophilic granuloma, Hand-Schuller-Christian disease, and Letterer-Siwe disease depends, therefore, on differences in the location, number, and extent of individual lesions and on the differing rates of progression of the disease. They should no longer be listed with the primary disorders of lipid metabolism, along with Niemann-Pick and Gaucher's disease. The etiology is unknown. It is quite possible that this group of diseases presents a common histologic picture produced by varying causes. A similar situation obtains in tuberculosis, sarcoidosis, and beryllium disease, where similar pathologic conditions result from widely differing etiologies.

Eosinophilic granuloma of the lung occurs usually in a young adult. Dyspnea and cough appear early, and eventually the patient appears chronically ill. While positive scalene lymph node and bronchoscopic biopsies have not been reported yet, positive histologic specimens may eventually be obtained by these methods. Therapy is as yet unsatisfactory. There have been reports of temporary remission with the use of antibiotics; later reports have shown antibiotics to be disappointing. Steroids have occasionally been observed to help. X-ray therapy has been useful for localized bone lesion.

Hematogenous Tuberculosis. During the acute phase of hematogenous pulmonary tuberculosis, the inflammatory involvement of the alveolar-capillary septa may produce alveolar-capillary block. In very advanced cases, sometimes a marked increase in the venous admixture is found. With effective antituberculous therapy, these abnormalities of oxygen transfer are reversed, correlating well with the resolution of the acute exudative process. In severe cases, after clinical recovery, a pattern of mild restrictive ventilatory insufficiency may persist, and pulmonary hypertension may occur with mild exercise (Mc Clement et al., 1951). This indicates that, in some instances, the scarring of healed miliary tuberculosis may be sufficient to result in the obliteration of a very large proportion of the pulmonary vascular bed. It is probable that eventually cases will be studied which will have gone on to the development of chronic cor pulmonale.

Wegener's Granulomatosis. Chronic cor pulmonale has been described in Wegener's granulomatosis. This is a disease of unknown etiology with pathologic changes suggestive of a hypersensitivity reaction. It is characterized by three features: (1) necrotizing granulomatous lesions in the upper and lower respiratory tracts, (2) generalized focal necrotizing vasculitis involving both arteries and veins, almost always present in the lungs, and often widely disseminated in other sites; (3) glomerulitis with necrosis, thrombosis, capsular adhesions, and granulomatous changes (Wegener, 1936, Fahey et al., 1954). The disease

diffusing capacity. More recently, however, it has been pointed out that the reduction in diffusion capacity in many of these cases is the result not merely of the thickening of the alveolar-capillary membrane but also of the *increased velocity of blood flow through a greatly narrowed vascular bed with consequent critical reduction in the alveolar-capillary contact time.* In such cases, the contact time between alveolus and blood becomes insufficient to allow equilibration between alveolar and capillary oxygen tensions. The result is a widening of the alveoloarterial oxygen tension gradient, reflected in a desaturation of arterial blood, i.e., a diffusion insufficiency (Rossier and Buhlmann, 1954, Luchsinger et al., 1957). The cases in this category also usually demonstrate moderate restrictive ventilatory dysfunction, lowered pulmonary compliance, reduced lung volumes, remarkably little reduction in maximum breathing capacity, and usually little or no abnormality in the distribution of inspired air However, Motley (1958) feels that some of the arterial blood oxygen desaturation on exercise in some of these patients is due to perfusion of blood through nonventilated or poorly ventilated areas These patients often show hyperventilation at rest and during exercise, resulting often in *low carbon dioxide tension* in the arterial blood Early, there is usually a normal arterial blood oxygen saturation at rest with marked reduction after exercise, eventually, resting *hypoxemia* develops, sometimes with *polycythemia,* which will increase the load on the right ventricle, just as it does in chronic diffuse obstructive emphysema (Austrian et al, 1951)

Early in the course of their disease, these patients may have a normal or only slightly elevated pulmonary arterial pressure at rest, developing a marked pulmonary hypertension on exercise. This is probably mainly the consequence of the anatomically narrowed pulmonary vascular channels which accommodate an increase in pulmonary flow by a marked increase in pulmonary arterial pressure However, some contribution to the pulmonary hypertension must also be made by the exercise-induced hypoxia. Eventually, pulmonary hypertension persists at rest. In the absence of cardiac failure, resting hypoxia, and polycythemia, *cardiac output in these patients is frequently found to be elevated.* It has been postulated that this high output in the absence of continual hypoxia is due to the increased metabolism resulting from the active interstitial inflammation in the lungs (Harvey et al, 1951), and the increased work of breathing, occasioned by the restrictive ventilatory defect. While most of these patients die of pulmonary insufficiency, some eventually develop marked arterial oxygen desaturation and right heart failure, at which time *cardiac output is found to be low.* The pulmonary hypertension in these conditions usually cannot be reversed

Sarcoidosis. The ways in which diffuse pulmonary involvement caused by extensive sarcoidosis may lead to chronic cor pulmonale have already been described. In the second type, the granulomas are located predominantly interstitially, compressing arterioles and capillaries, as well as markedly thickening the alveolar-capillary membrane (see above). It should be stressed again that a complicating picture of diffuse obstructive emphysema may also be present, although a relatively "pure" form of alveolar-capillary block may be produced by this type of pulmonary sarcoidosis (Coates and Comroe, 1951; McClement et al, 1953, Stone et al, 1953, Marks et al., 1957).

Beryllium Disease. Beryllium disease with diffuse involvement of the lung may produce pathologic and functional derangements identical to those of sarcoidosis (Austrian et al, 1951, Marks et al., 1957). The term "beryllium disease" is preferable to the terms "pulmonary granulomatosis of beryllium workers" or "berylliosis" because the disease is truly a systemic intoxication, with biochemical abnormalities and involvement of the liver, spleen, kidney, and myocardium, as well as the lung.

The mechanism of disease production is comparable to that of a chemical intoxication, such as in lead poisoning, with changes attributed to hypersensitivity phenomena, rather than to a reaction, as in the pneumonoconioses The term berylliosis is completely misleading, because the disease is not produced by the inhalation of beryl ore The disease-producing substances include beryllium metal, beryllium oxide, alloys of beryllium with other metals, and acid salts of beryllium While a history of exposure to beryllium, as in certain incriminated industrial operations, is extremely helpful, the diagnosis of beryllium disease can be proved only by discovery through spectrographic or chemical me[illegible] ,llium in

ent (see below). While basal subcrepitant rales are audible, there is a striking paucity of physical signs in view of the x-ray findings. Roentgenologically, there is usually an increase in the density of the hilar and vascular markings, with eventually bilateral diffuse reticular mottling and superimposed fine nodulation. With intercurrent infections, infiltrations due to bronchopneumonitis appear. *Clubbing* is frequent. *Polycythemia* may be present, especially late. The major physiologic disturbances are those that occur with the alveolar-capillary block syndrome and moderate restrictive ventilatory dysfunction. Death is usually due to pulmonary insufficiency, right heart failure, or terminal bronchopneumonitis. Treatment should always include the use of the adrenal corticosteroids or their analogues, because of their known retarding effect on fibroblastic proliferation. However, until tried, it is impossible to predict their effectiveness in any single patient. Sudden death has been described following the abrupt termination of steroid therapy (Rubin and Lubliner, 1957).

Idiopathic Pulmonary Hemosiderosis. Idiopathic pulmonary hemosiderosis (Ceelen's pulmonary hemosiderosis) may cause chronic cor pulmonale. The etiology is unknown.

The lung shows an increase in reticulum, collagen, and smooth muscle, fragmentation of the elastic tissue in the alveolar walls and small blood vessels, and recent and old hemorrhages, with many hemosiderin-filled macrophages. There is a marked increase in the amount of iron in the lung. Severe interstitial fibrosis and thickening of the alveolar walls eventually develop. Cases have been mistaken for the Hamman-Rich syndrome.

Idiopathic pulmonary hemosiderosis usually occurs in children and young adults. Acute episodes are characterized by severe cough with massive hemoptysis and dyspnea. Remissions and exacerbations are characteristic. There then develop increasing exertional dyspnea, easy fatigability, severe anemia and reticulocytosis, and sometimes jaundice. Siderocytes may be seen in the sputum and in a lung biopsy. Chronic cor pulmonale with right heart failure frequently develops. Death is usually from respiratory failure.

Radiation Fibrosis of the Lungs. Chronic cor pulmonale has been reported in radiation fibrosis of the lungs (radiation pneumonitis). Usually, it is a large amount of radiation given in a brief period of time to both lungs that leads to this condition. The damage begins with injury to the alveolar walls and capillary endothelium, with edema, followed by proliferation of alveolar and capillary endothelium and fibroblastic proliferation in the alveolar walls. This is followed by obliteration of the alveoli, with marked thickening of the alveolar capillary septa, peribronchial and perivascular fibrosis, and disruption of pulmonary elastic tissue. The pathologic picture is aggravated by the development of bronchial obstruction due to bronchial reaction with areas of atelectasis and pneumonitis (Warren and Spencer, 1940, Brown, 1956). The pattern of pulmonary dysfunction is that of the alveolar-capillary block syndrome with a markedly reduced or restricted pulmonary vascular bed (Stone et al., 1956). When the damage is severe, such patients show progressively severe dyspnea and productive cough, fever, right heart failure, and pulmonary insufficiency.

Diffuse Pulmonary Interstitial Fibrosis Caused by Obstruction of the Pulmonary Veins. There have been reports of an unusual form of interstitial pulmonary fibrosis due to chronic obstruction of the pulmonary veins. The most common cause of the pulmonary venous obstruction has been a dense collagenous or keloid-like mass in the mediastinum, apparently a result of a healed posterior mediastinitis. Chronic pulmonary venous obstruction with similar pulmonary changes, due to a large myxoma of the left atrium, a large left atrial thrombus, or congenital stenosis of the pulmonary veins, has also been reported. The extensive pulmonary changes are usually seen only in the portions of the lung in which pulmonary veins have been constricted by the collagenous mass in the mediastinum. When the process is extensive enough, chronic cor pulmonale develops (Edwards and Burchell, 1951, Andrews, 1957; Bindelglass and Trubowitz, 1958). In its most fully developed form, the interstitial pulmonary fibrosis is found to be identical to that occurring in the late stage of the Hamman-Rich syndrome.

Andrews suggests that in any case of unexplained pulmonary interstitial fibrosis, the pulmonary veins and their atrial orifices be very care-

appears usually in patients in the fourth and fifth decades of life, without histories of allergy, asthma, or exposure to sulfonamides. The onset is frequently with a severe or often destructive sinusitis or rhinitis, followed by what appears to be a persistent pneumonitis. Signs of renal damage and generalized vasculitis accompany or follow these respiratory symptoms. Pulmonary hypertension and chronic cor pulmonale develop frequently. Specific involvement of the myocardium and the presence of pulmonary infarction due to vascular occlusion may complicate the picture (Fahey et al., 1954). The disease is usually fatal, running a course of from 6 months to 2 years.

Pneumonoconiosis. In severe *asbestosis, extensive interstitial fibrosis* is the main cause of the pulmonary hypertension and the resultant chronic cor pulmonale.

In *silicosis,* chronic cor pulmonale develops much more frequently when there is the complicating presence of *diffuse obstructive emphysema,* and here the changes are like those in chronic cor pulmonale due to chronic obstructive emphysema alone, except that the cardiac output tends to be normal or low (Thomas, 1951, Harvey et al., 1951, Wells, 1954b). However, chronic cor pulmonale has occasionally been recorded in silicosis without significant chronic obstructive emphysema, where the silicotic nodules appear to be located mainly about vascular channels, often also with extensive conglomerate scarring. Here, usually, arterial oxygen desaturation is *not* present at rest, appearing only on exercise; cardiac output tends to be normal or low (Harvey et al, 1951). *Thrombosis of the major branches of the pulmonary artery* frequently occurs in severe silicosis and contributes to the reduction in the pulmonary vascular bed (Wells, 1954)

Collagen Diseases (see Part 16, Chap 3). Chronic cor pulmonale has been observed in scleroderma when the involvement of the lung has been diffuse and severe (Taubenhaus et al, 1955). It is associated with the syndrome of alveolar-capillary block (Austrian et al., 1951). Cases of dermatomyositis have been reported in which degenerative and occlusive changes in the small pulmonary arteries and arterioles caused severe pulmonary hypertension and right ventricular hypertrophy (Cald well and Aitchison, 1956). Disseminated lupu erythematosus has been noted occasionally t be associated with sufficient pulmonary vas cular involvement to cause chronic cor pu monale (Wood, 1952).

Diffuse Interstitial Pulmonary Fibrosis. Di fuse interstitial pulmonary fibrosis (Hammar Rich syndrome) usually causes chronic c pulmonale. The etiology is unknown Wh clinically and pathologically the end stages this syndrome represent an entity, it is mo probable that it is in fact a heterogeneo group, with many etiologies.

Early, there is a *non-granulomatous interstit pneumonitis* associated with marked hyperpla and metaplasia of the alveolar cells, sufficien striking sometimes to resemble adenomatosis. T inflammatory changes in the alveolar walls co tinue to the eventual deposition of fibrous tiss with further thickening of the alveolar walls, that they may encroach on the alveolar spac Usually, very little inflammatory exudate is se in the alveoli, except in the presence of a comp cating bronchopneumonitis. Eventually, diff induration of both lungs with a fine meshwork relatively acellular fibrous tissue occurs Howev even in far-advanced cases, foci may be se showing the exudative and cellular features scribed above and indicating continued activity of the disease process (Hamman and Rich, 1944, Schechter, 1953, Rubin and Lubliner, 1957) The focal scarring, emphysematous bleb formation, and bronchiolar necrosis often evolve into the picture of shrunken fibrotic lungs with multiple small air cysts, bronchiolectasis, and bronchiectasis (honeycomb lung) (Oswald and Parkinson, 1949, Rubin and Lubliner, 1957).

This condition is more common in males; it occurs most frequently between the ages of 30 and 50 but has been reported at all ages The duration of symptoms varies from 6 months to over 6 years. It is apparent that by the time severe symptoms appear, the disease has been present for many months and often years Clinically, there is progressive dyspnea and cyanosis, thoracic pain, frequent hemoptysis, and a nonproductive cough. Weight loss and fever occur, especially when there is superimposed pneumonitis Eventually expectoration appears, becoming profuse and occasionally bloody. The usual physical signs associated with pulmonary hypertension are pres-

nized as acute cor pulmonale (Mack et al., 1950).

COMBINATIONS OF TYPE I THROUGH TYPE III

In many instances, structural and functional abnormalities of more than one category may coexist in a patient, contributing to the development of chronic cor pulmonale. For example, in *sarcoidosis*, even when the involvement tends to be localized primarily about the pulmonary vessels, there may be sufficient peribronchial granulomatous infiltration to have produced a significant degree of diffuse obstructive emphysema. However, examples in which the involvement is almost exclusively of one or the other type have been reported. In *silicosis*, too, while predominant vascular involvement is very important, the complicating diffuse obstructive emphysema is often the major reason for the development of chronic cor pulmonale. In some cases of severe *kyphoscoliosis*, functional abnormalities pertinent to all three categories exist. For example, a case of severe kyphoscoliosis may show some anatomic reduction of the pulmonary vascular bed, particularly in areas where there is compression of the lung, alveolar hypoventilation due to marked restriction of the chest bellows, and diffuse airway obstruction with chronic obstructive emphysema.

DIAGNOSIS

It is almost impossible to make an early diagnosis of chronic cor pulmonale because of the difficulties in recognition of early right heart enlargement. While pulmonary hypertension must exist for some time before right ventricular hypertrophy develops, its clinical recognition in a patient with chronic pulmonary disease justifies the presumptive diagnosis of chronic cor pulmonale.

Clinical Examination. Clinical evidence of chronic cor pulmonale appears late in the course of the disease. In chronic diffuse obstructive emphysema, the overdistended lungs make it difficult to detect the usual signs of pulmonary hypertension and right ventricular enlargement. The heart tones are often faint. The existence of chronic cor pulmonale should, therefore, be suspected in patients with chronic obstructive emphysema of more than minimal degree. By the time arterial blood gas abnormalities become demonstrable, chronic cor pulmonale may be assumed to be present. The presence of *secondary polycythemia* is thus usually good evidence that right ventricular hypertrophy has already developed (Harvey et al., 1951).

Clubbing of the digits and pulmonary hypertrophic osteoarthropathy do not necessarily indicate the presence of chronic cor pulmonale since they may occur with small local lesions in the lung, such as bronchogenic carcinoma or fibrous mesothelioma. They are more frequently present when severe suppurative bronchiectasis coexists with the diffuse obstructive emphysema.

The mechanisms involved in the production of clubbing of the digits are as yet poorly understood. However, it has been demonstrated that an *increased blood flow* exists through the clubbed digits which is in excess of physiologic requirements and is largely passing through the numerous arteriovenous anastomoses in the distal segments. The direct passage of blood from digital arteries into the deep venous plexus of the digits is held to account for the structural changes observed in clubbed digits. Clubbing is a reversible condition, and in those conditions where a reduction of the circulation to the fingers is possible, regression of the clubbing occurs. This has been reported after the removal of pulmonary tumors (Mendlowitz, 1942, Wilson, 1952).

Arrhythmias, with the exception of nodal tachycardia, are unusual in chronic cor pulmonale. *Pleural effusions* due to congestive failure are rare; if they occur, a postpneumonic empyema or pulmonary infarction should be suspected. *Moderate elevation of peripheral venous pressure* in the absence of congestive heart failure may occur because of the increased intrapleural pressure present in many patients with chronic obstructive emphysema; however, marked elevation of venous pressure is usually a sign of right heart failure. By the time the usual peripheral signs of right ventricular failure appear, the recognition of right heart involvement becomes easy.

When overdistended lungs or thoracic deformity do not interfere with the examination, and when the pulmonary artery pressure is quite high, striking findings often appear. This is especially true in such conditions as multiple recurrent small pulmonary emboli and primary pulmonary hypertension. Examina-

fully examined. He also pointed out the similarity of the changes of this condition with those that occur in idiopathic pulmonary hemosiderosis. There are dense interstitial fibrosis with marked thickening of the alveolar capillary membrane, and marked narrowing of many of the arterioles and smaller arteries by medial hypertrophy and intimal proliferation. Some of the vascular narrowing is clearly the result of thrombosis However, such thrombotic changes are secondary, since it is known that pulmonary arterial and arteriolar thromboses do not produce interstitial fibrosis of this type. Where there is sparing of the pulmonary veins of one or more lobes, these lobes show normal arteries, arterioles, and the absence of the interstitial fibrosis

Edwards and Burchell postulated that the occlusive arterial and arteriolar lesions in the lobes with severe venous obstruction act to protect the pulmonary capillaries from excessive passive congestion This condition cannot be reproduced experimentally by acute obstruction of the pulmonary veins, since apparently chronic long-standing obstruction is necessary. The clinical picture is not sufficiently typical to make the diagnosis readily. Varying murmurs may be heard over the heart. Most striking is the development of progressive dyspnea, cough, and repeated massive hemoptyses. There may be *recurrent pulmonary edema*, and eventually intractable right heart failure develops (Andrews, 1957, Bindelglass and Trubowitz, 1958)

Polycystic Disease of the Lungs. Diffuse polycystic disease of the lung, sometimes described as *honeycomb lung*, is often the end stage of many conditions in which there is diffuse interstitial infiltration of the lung with eventual development of interstitial fibrosis (Oswald and Parkinson, 1949). It has thus been observed in sarcoidosis, histiocytosis X, diffuse granulomas of unknown etiology, and the Hamman-Rich syndrome Cases of diffuse involvement of the lung with miliary cysts satisfying the criteria for congenital hereditary origin have been described by McKusick and Fisher. Similar congenital cystic disease of the lung has been observed in Marfan's syndrome and tuberous sclerosis. These patients develop recurrent pneumonitis and often spontaneous pneumothorax Carcinomatous degeneration has been reported. McKusick and Fisher stress the fact that the pulmonary lesions may be completely silent, escaping clinical detection for many years. However, clubbing of the digits or more advanced types of hypertrophic pulmonary osteoarthropathy may be present in these patients for many years before subjective or objective pulmonary signs appear

Metastatic Carcinomatosis of the Lung. Metastatic carcinomatosis of the lung may lead to chronic cor pulmonale in several ways Extensive perivascular lymphatic spread (endolymphatic carcinomatosis or lymphangitic carcinomatosis) often causes a carcinomatous endarteritis as well as external mechanical compression of the arteries and arterioles by the desmoplastic character of the cords of carcinoma cells (Storstein, 1951). Extension into the interalveolar septa may also produce varying degrees of alveolar-capillary block. Multiple emboli, composed of either tumor tissue or blood clots from the deep leg veins, may further reduce the pulmonary vascular bed. Local vascular thromboses in the lung also often occur to reduce further the vascular bed. Occasionally, distention of the pulmonary lymphatic vessels may give rise to the presence in the x-ray of horizontal linear densities in the periphery of the lung bases (Levin, 1959). In extensive carcinomatosis, the presence of severe anemia may prevent the appearance of central cyanosis. When the progression of events leading to right heart enlargement and failure is very rapid, the term *subacute cor pulmonale* has been applied (Greenspan, 1934, Brill and Robertson, 1937; Mason, 1940)

Other Diffuse Interstitial Infiltrations of the Lung. Also reported to cause chronic cor pulmonale are the following conditions: far-advanced farmer's lung, pulmonary interstitial granulomatosis of unknown etiology, and diffuse bronchiolar carcinoma of both lungs (adenomatosis)

Extrinsic Compression of the Main Pulmonary Arteries. Compression of the main pulmonary artery trunk or its stems has been recorded to cause chronic cor pulmonale. This has been described with an aneurysm of the concave portion of the ascending aorta and with tuberculous calcified or neoplastic hilar lymph nodes Should rupture of the aneurysm of the aorta into the pulmonary artery occur, this sudden development of a left-to-right shunt will lead to all the abnormalities recog-

Electrocardiography. Like all other techniques, the electrocardiogram gives evidence for the diagnosis of chronic cor pulmonale late; it does, however, give such evidence earlier than the roentgenogram. In addition to the usual leads, special precordial leads over the right chest (V_4R, V_5R) give valuable additional information The changes most frequently seen in chronic cor pulmonale due to chronic obstructive emphysema are those which are not themselves pathognomonic of right ventricular hypertrophy. As a result of the overdistended lung and the depressed diaphragms in chronic obstructive emphysema, *the heart assumes a more vertical position, and is rotated clockwise about its longitudinal axis, sometimes with backward displacement of its apex*

This is usually manifested in a mainly inverted *QRS* complex in aVL and an upright QRS complex in aVF, and a shift of the transitional zone over the precordium to the left, with the presence of S waves in all the limb leads and the persistence of S waves *in* leads V_5 and V_6 Sometimes the QRS complex will be of *the QS type in* V_2 *and* V_3, because of the marked clockwise rotation *of* the heart, and may simulate the residual *changes of* an old transmural anteroseptal infarct The QRS complexes may sometimes exhibit *low voltage,* especially in the precordial leads. This may be because of the increased volume of air-containing lung between the heart and chest wall, or because of a positional change in the heart, so that the direction of the QRS vector becomes *perpendicular* to the frontal plane All these changes often simulate or are exaggerated by the presence of right ventricular hypertrophy or dilatation, since right ventricular enlargement will produce the same kind of rotation of the heart as the pulmonary changes associated with chronic emphysema (Zuckerman et al, 1948).

When, in a patient with *chronic obstructive* emphysema, *P pulmonale* is present with these changes, the diagnosis of *chronic cor pulmonale* becomes extremely likely, even though these changes per se are *not the result* of hypertrophy of the right ventricle

P pulmonale (Shleser and Langendorf, 1942, Katz and Pick, 1956) is a tall, peaked P wave in leads II, III, and aVF (Fig 13-28) Usually it is also seen to be small in lead I, inverted in aVL, and often diphasic (plus-minus) *in* V_1 *and* V_2 It is often associated with a depression of *the* P-Q segment owing to the prominent negative T_p waves This is apparently a secondary T-wave change, since it is associated with a high-voltage upright P wave. The exact mechanism for its production is unknown While in some cases, it may be associated with hypertrophy or dilatation of the right atrium, it frequently is present when *these are absent. In* some patients, P pulmonale will *revert to* normal after intensive treatment. In most cases, it is probably *due to a positional* change, in a markedly vertical heart with a low diaphragm, the apex is displaced *in such a way* that higher upright P-wave potentials, ordinarily facing towards the back or other parts, are now directed to the feet.

It has been reported in normal persons that complexes with secondary R waves (*r'*) *are found* in V_4R in about 50 per cent of cases. If more *right-sided* leads are taken (V_5R, V_3R, *and an* interspace above and below as well), more than 50 per cent show an r'. These are especially frequent when the leads are *placed* one interspace below However, in normal persons, usually the S wave is larger than either R deflection, and usually the r' is smaller than the R (*Camerini* and Davies, 1955). Probably the r' represents activation of the conus of the right ventricle, since it has been known for some time that the conus of the right ventricle and the posterobasal portion of the left ventricle are the last parts of the myocardium to be activated (Lewis and Rothschild, 1915, Barker et al, 1930).

The appearance of an M-shaped QRS complex (rsR'), with R' *taller* than r, in leads over the right precordium (V_4R, V_1, and V_2), which has been called *incomplete right bundle branch block* by *some* investigators, is usually good evidence *of right* ventricular "strain" and hence of chronic cor pulmonale (Fig 13-27). *In* some cases, complete right bundle branch block, with QRS duration longer than 0.12 sec, may also result *from* right ventricular involvement *in* chronic *cor* pulmonale.

The presence of a *typical* right ventricular hypertrophy pattern (a relatively tall, late R *in* V_4R or V_1) *is* usually definite evidence of chronic cor pulmonale (Myers et al, 1948) (Fig 13-28). *An R wave in* aVR is not sufficient The tall R *may sometimes* be preceded by a tiny Q wave.

The relationship between the type of *overload on the right ventricle* and the type of electrocardiographic evidence of heart *strain* has been described by Cabrera and Monroy,

tion of the heart may reveal displacement of the apex beat to the left, but with an enlargement of the right ventricular type, i.e., a systolic heave over the right ventricular outflow tract. *The 2d sound at the pulmonic area is loud and split,* and often easily palpable. Various murmurs are frequently heard and are often difficult to differentiate from those present in congenital or acquired heart disease. A *systolic murmur* over the base is common. Frequently present is *the Graham-Steell murmur* of pulmonary insufficiency. A *mid-diastolic murmur* may be heard in the 4th left interspace or over the apex; it probably corresponds to a "right-sided Austin-Flint murmur." Wood (1952) has stressed that the peripheral pulse is usually small and the systemic blood pressure low, with the systolic and diastolic pressures approaching the mean He also has stressed the appearance of *giant A waves* in the jugular venous pulse. Left vocal cord paralysis, due to compression of the left recurrent laryngeal nerve by a dilated main or left pulmonary artery, has been noted.

Roentgenologic Examination. Roentgenologic signs of chronic cor pulmonale, while also rather late in appearing, are suggestive earlier than the clinical findings In addition to the usual roentgenographic studies (posteroanterior, both oblique, and lateral projections), careful fluoroscopic examination is of special value because it may aid in the simultaneous assessment of pulmonary function The earliest abnormality to become apparent is *enlargement of the pulmonary artery trunk and its main stems* This abnormal dilatation is due to the pulmonary arterial hypertension, and must be differentiated from the normal prominence of the pulmonary artery trunk in a vertically placed heart, which is rotated clockwise about its longitudinal axis This positional change of the heart is the usual one occurring in chronic obstructive emphysema, in which the diaphragm is depressed and the lungs are overdistended The enlargement of the pulmonary artery trunk is best seen with the patient in the right anterior oblique position. When the dilatation becomes more marked, it becomes visible as a convexity of the left middle salient in the posteroanterior projection Hilar dance is usually not present, since the degree of augmentation of pulmonary blood flow necessary to produce this phenomenon is usually not found in chronic cor pulmonale. Calcification of pulmonary arterial atheromas may rarely be seen. *Right ventricular enlargement* usually is first seen in the right anterior oblique and lateral projections as an anterior bulging in the region of the outflow tract or pulmonary conus of the right ventricle, encroaching on the retrosternal space. It should be noted that by the time the enlargement of the right ventricle is demonstrable in x-rays, dilatation is already present, *hypertrophy of the free wall of the right ventricle alone cannot be detected roentgenologically in chronic cor pulmonale.* If concomitant marked left ventricular enlargement is present, the detection of associated right ventricular enlargement may be difficult, because retrosternal encroachment by the enlarged left ventricle may simulate that due to an enlarged right ventricle. An increase in the transverse diameter of the heart in the posteroanterior projection usually appears very late or not at all, and is due to displacement of the left ventricle; the right ventricle is still anteriorly located and never forms part of the left border of the cardiac silhouette in this view. The development of congestive failure will often make apparent a dilated superior vena cava and an enlarged right atrium. Except for its occasional use to exclude congenital heart disease or to localize an arteriovenous fistula in the lung, angiocardiography has not been particularly useful in the diagnosis of chronic cor pulmonale

Cardiac Catheterization (see Chap. 4). Right heart catheterization is the best method for the early detection of pulmonary hypertension. While it cannot be recommended as a routine diagnostic procedure, its use in combination with pulmonary function tests and blood gas studies may be very helpful in management It may be necessary to rule out the presence of congenital heart disease or mitral stenosis While the presence of pulmonary hypertension is not *prima facie* evidence of the presence of right ventricular hypertrophy, for practical purposes, its presence, especially at rest, in a patient with considerable chronic pulmonary disease justifies the assumption that right ventricular hypertrophy has already developed.

wise rotation of the heart about its longitudinal axis) or *ischemia of the anterior wall of the heart* That the first mechanism is probably operating most often is borne out by the observation that after successful treatment in some cases, not only do these T waves become upright, but a shift in the transitional zone over the precordium to the right, and a reduction in size of the S waves in the limb leads and in V_5 and V_6 also occur. This is not associated with demonstrable change in position of the diaphragm, but congestive failure has been eliminated, and hence presumably right ventricular dilatation has been reduced. Absence of a prolonged Q-T interval may help rule out anteroseptal infarction when the T waves are inverted over the right precordium, since it has been reported that the Q-T interval is normal in patients with chronic cor pulmonale in the absence of other types of heart disease (Alexander et al., 1951).

TREATMENT

The treatment of chronic cor pulmonale today has much to offer. The unselective pessimistic attitude of the past arose from a failure to differentiate among the various causes of chronic cor pulmonale, the imperfect understanding of the pathologic physiology of the condition, and the failure to separate symptoms due to the pulmonary disease from those due to cardiac failure. Moreover, newer techniques in the treatment of bronchopulmonary disease are now available. When the chronic cor pulmonale is due to diffuse obstructive emphysema, in which many of the pathologic and physiologic changes are partially reversible, real improvement will frequently result from

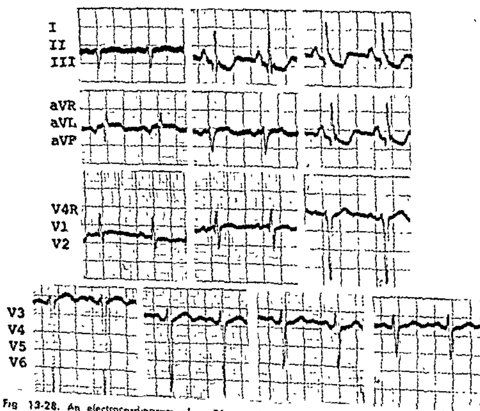

Fig 13-28. An electrocardiogram of a 56-year-old male patient with bronchiectasis, severe chronic diffuse obstructive emphysema, and chronic cor pulmonale (necropsy) Sinus rhythm P pulmonale The QRS complex is mainly inverted in leads I and aVL, and upright in leads II, III, and aVF, an R wave is present in aVR The S-T segment is depressed in leads II, III, and aVF, and slightly elevated in aVR and aVL Electric position is vertical A tall late R' wave is present in leads V_4R and V_1, preceded by a tiny r and s. A deep S wave persists out to V_6 There is a marked shift of the transitional zone over the precordium to the left. This is a right ventricular hypertrophy pattern

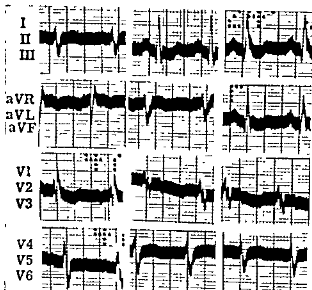

Fig. 13-27. An electrocardiogram of a 53-year-old male patient (I C.) with bronchiectasis, chronic diffuse obstructive emphysema, secondary polycythemia, and chronic cor pulmonale Sinus rhythm The QRS complex is mainly inverted with a broad S wave in leads I and aVL, and upright in leads II, III, and aVF. A late R wave is present in aVR The S-T segment is depressed in leads II, III, and aVF, and slightly elevated in aVR and aVL Electric position is vertical An M-shaped QRS complex is present in leads V_1 and V_2 (rsR'). A deep broad S wave is present in leads V_4 through V_6. There is a marked shift of the transitional zone over the precordium to the left. This is so-called incomplete right bundle branch system block, and is good evidence for right ventricular hypertrophy

and Donzelot et al. For example, in interatrial septal defect, a "diastolic overload" pattern is usually seen (rsR'), while in congenital pulmonic stenosis a "systolic overload" pattern is usually found (tall R wave over right and much of left precordium, with depressed S-T segment and inverted T wave). The first type of right ventricular enlargement pattern ("diastolic overload," i e , rsR' over the right precordium) occurs somewhat more frequently in chronic cor pulmonale due to chronic obstructive emphysema (Fig 13-27), while the second type ("systolic overload," i.e , tall, late R wave over the right precordium) occurs more often in chronic cor pulmonale due to pulmonary disease with predominant involvement of the vessels (Mack and Snider, 1956) This may be a manifestation of the greater frequency of *augmented input loading* of the right ventricle in the first type of chronic cor pulmonale, in which hypervolemia and increased cardiac output are more common However, this simple relationship is complicated by the fact that in chronic cor pulmonale due to chronic obstructive emphysema, resistance overloading also occurs because of the increase in pulmonary vascular resistance and pressure. Moreover, with the development of right ventricular failure and dilatation of the right ventricle, diastolic overload occurs even in chronic cor pulmonale due to pulmonary disease, in which the pathologic condition is largely localized in or about the pulmonary vessels.

Suggestive electrocardiographic changes and those definite for right heart hypertrophy occur in chronic cor pulmonale only when the hypertrophy is marked. When electrocardiographic evidence of right ventricular hypertrophy is present, the latter is almost always found at necropsy (Myers et al., 1948; Johnson et al., 1950), but in the majority of cases, particularly when the hypertrophy is slight or moderate, no definite right ventricular hypertrophy pattern is seen in the electrocardiogram. Not all the reasons for the electrocardiographic changes in right ventricular hypertrophy are yet understood. While positional changes are important in influencing the contour, they are certainly not the sole cause. The mechanism by which an acute increase in work of the right ventricle, usually associated with dilatation of the chamber, produces the so-called "strain pattern" is also not understood

The spatial vectorcardiogram in some cases may show a typical pattern of right ventricular hypertrophy when the electrocardiogram is equivocal or negative. It may also help differentiate right ventricular hypertrophy from right bundle branch block (Elek et al, 1954, Stern and Tenney, 1956). However, the changes in heart position produced by diffuse obstructive emphysema often obscure the pattern of right ventricular hypertrophy in the spatial vectorcardiogram (Stern and Tenney, 1956). Frequently the presence of a right ventricular strain pattern is associated with the presence of inverted T waves in leads V_2 through V_4. These often become upright after treatment. The reason for the inversion of these T waves is not fully understood as yet They may be caused by *right ventricular dilatation* (reflecting merely an increased clock-

trations, intermittently, well-humidified, and only if the patient is under constant observation by a physician Control of the oxygen therapy will depend on its observed effect on the frequency and depth of respiration, the clinical appearance of the patient, and finally, wherever possible, on serial determinations of the arterial blood gases. The latter techniques are important, since the clinical appearance of the patient may be deceptive If arterial blood gases cannot be measured, the carbon dioxide content and pH of the venous blood will be of some aid It is often necessary to use some *mechanical aid to respiration* in order to hyperventilate the patient, in an attempt to "wash out" retained carbon dioxide at the same time that oxygen is being administered The various types of *intermittent positive-pressure respirators* are useful in this regard.[2] Some of them require the patient's own spontaneous inspiratory effort to start the inspiratory cycle, and, if the patient's respiratory rate is adequate, they may be used with oxygen. However, if the patient tends to develop respiratory depression or apnea, a compressed air tank may be substituted for the oxygen tank, or an apparatus used which cycles automatically. When the situation is more critical, it may be necessary to use a *tank respirator*, a measure which requires meticulous nursing care and constant attention (Boutourline-Young and Whittenberger, 1951; Barach et al, 1952, Harvey et al, 1953, Segal and Attinger, 1955) Mechanical respiratory aid may have to be continued, usually intermittently, for several weeks, since the carbon dioxide stores in the body are not confined to the blood alone but include those present in all the body fluids as well, especially the fat (Nichols, 1957).

Respiratory depressant drugs, such as *morphine*, are strongly contraindicated When the patient's condition becomes less critical, attempts should be made to improve his ventilatory function by training him in the more effective use of his diaphragm (*breathing exercises*, Miller, 1953), pneumoperitoneum and abdominal belts have been disappointing in their results.

Mechanical cough devices, devised by Barach and Beck (1954), using exsufflation with negative pressure, have been useful to produce hyperventilation and to raise secretions from the tracheobronchial tree. A *tracheostomy* may be required to permit removal of secretions which the patient cannot raise, it will also diminish the dead space. It may be used with an intermittent positive-pressure breathing apparatus. In some cases, the tracheostomy becomes permanent. Overholt and Segal have employed elective long-term tracheostomy in some patients with extensive bilateral bronchiectasis. For patients requiring permanent tracheostomy and repeated catheter aspiration of the deeper airways because of ineffective cough and profuse secretions, an operation developed by Rockey and associates (1956) holds promise. It involves the creation of a skin-lined cervical tracheocutaneous communication guarded with airtight external skin valves (tracheal fenestration). It permits phonation and cough but can be opened at will for aspiration.

The carbonic anhydrase inhibitor, *acetazoleamide*, has sometimes proved useful in the treatment of patients with chronic cor pulmonale and hypercapnia, with or without congestive failure (Nadell, 1953, Bell et al., 1955, Galdston and Geller, 1957). This drug decreases the alkali reserve (plasma bicarbonate) by promoting the excretion of bicarbonate and bicarbonate-bound base by the kidney. Because it produces a metabolic acidosis, it should *not* be used in the presence of severe acidosis Acetazoleamide also decreases the partial pressure of carbon dioxide in the arterial blood. This is probably because of improved alveolar ventilation, since the drug has been reported to increase the response of the respiratory center to the carbon dioxide stimulus, especially if intravenous aminophylline is also given (Taquini et al, 1957; Galdston and Geller, 1957). Acetazoleamide also acts as a mild diuretic, being more efficient in the congestive failure of chronic cor pulmonale than in that associated with other types of heart disease (Schwartz et al, 1955). It has also

hypoventilation

While there has been good evidence that *salicylates* in large doses stimulate respiration (Tenney and Miller, 1955; Wegria et al.,

[2] It should be kept in mind that, if used continuously, these respirators will tend to decrease cardiac output.

treatment. Where the chronic cor pulmonale is due to pulmonary disease with the pathologic condition localized mainly in or about the pulmonary vessels, the outlook for treatment is less favorable.

Treatment of Chronic Cor Pulmonale Due to Chronic Diffuse Obstructive Emphysema. Intensive treatment of the bronchopulmonary disease is as important as, and usually more important than, specific cardiac measures. Congestive heart failure can be alleviated only by at least partial reversal of many of the pathologic changes in the lung which are responsible for the anatomic reduction in the pulmonary vascular bed and the hypoxia. This is accomplished by combating infection, producing an adequate airway, and improving effective alveolar ventilation These goals are interdependent, so that the measures employed have multiple effects

Antibiotics should be given promptly in an attempt to control infection, which frequently was the precipitating cause of the breakdown. The sputum should be cultured, and sensitivities of the significant organisms to various antibiotics determined However, one should not wait for the results of such studies before administering antibiotics. Necessary changes of the antibiotic may be made after the results of the sensitivity studies are known

Tetracycline appears in the sputum in high concentration and is especially useful, if *penicillin* is given by injection, it should also be administered by *aerosol*, since it is not excreted in the sputum sufficiently. Resistant micrococci have been unusually troublesome and, if present, will require treatment with such drugs as *chloramphenicol, erythromycin*, or *novobiocin*.

Bronchodilator drugs are invaluable for aiding bronchial drainage, helping control infection, and improving ventilation The sympathomimetic amines, isoproterenol (*Isuprel*), racemic epinephrine (*Vaponephrin*), and phenylephrine (*Neo-synephrine*), are best given by *aerosol*, usually mixed with normal saline solution or a detergent solution, at least four times daily. Where effective inhalation does not occur, intermittent positive-pressure breathing devices may be useful to help deliver the aerosol. Theophylline ethylenediamine (*aminophylline*) is very useful, especially when given, well diluted, by slow intravenous drip; it is also effective when given rectally, especially as a retention enema. *Ephedrine* orally is also an effective bronchodilator. It may be necessary to use corticotropin, adrenal corticosteroids, or their analogues, but their potential disadvantages should be recognized

Sputum liquefaction is aided by overcoming dehydration, humidification of room air, and frequent inhalations of mist produced by the nebulization of water or detergent solutions. If the sputum is unusually purulent and viscid, aerosols containing *proteolytic enzymes* (*pancreatic dornase*) may be helpful. *Potassium iodide* is an excellent expectorant Cough and expectoration should be facilitated. Antitussive medication should be used minimally or not at all. Where basal bronchiectasis is present, *postural drainage* may be of great help, although the patient is often too sick to permit it *Endotracheal aspiration* with a soft rubber catheter may be lifesaving; in some cases, bronchoscopy and even tracheostomy will be necessary.

The respiratory center in these patients is usually unresponsive to either increased partial pressure of carbon dioxide or increased hydrogen ion concentration in the arterial blood, apparently because of a selective depression of the respiratory center to these stimuli. If the hypercapnia has been of long duration, this poor ventilatory response to the carbon dioxide stimulus is usually not reversible, even though the partial pressure of carbon dioxide and the alkali reserve in the arterial blood are restored to normal levels (Tenney, 1954; Cohn et al, 1954; Fishman et al , 1955). Yet the respiratory center still responds to afferent stimuli from special receptors in the muscles, since exercise still causes increased ventilation. It is also still responsive to afferent stimuli from the carotid and aortic bodies, so that the tachypnea, which is necessary in these patients, is often maintained mainly by some degree of hypoxemia. *The use of pure oxygen consistently depresses ventilation*, thus having a different effect than when given in concentrations sufficient merely to correct the hypoxemia towards the physiologic range (Fishman et al., 1955). *The use of 100 per cent oxygen may thus lead to hypoventilation, with carbon dioxide retention, acidosis and death*. Nevertheless, because of the disastrous consequences of severe hypoxemia, the administration of oxygen is frequently mandatory. It should then be given *in lower conce*

ties, they frequently herald impending pulmonary and circulatory breakdown These may be prevented by intense therapy. While the acute respiratory infection which often initiates a downhill course in these patients is usually originally of viral origin, it is the bacterial superinfection which lingers and is eventually the most disturbing For this reason, in those patients in whom repeated respiratory infections occur, the use of small doses of broad-spectrum antibiotics, daily or several times weekly, especially during the winter, may be very valuable (McVay and Sprunt, 1953). It is often advisable to interrupt such prophylactic treatment periods to permit the reestablishment of normal saprophytic flora

Treatment of Chronic Cor Pulmonale Due to Chronic Alveolar Hypoventilation Syndromes. In this group of conditions, treatment of right heart failure includes the usual cardiac measures and phlebotomy However, no success will be achieved unless alveolar ventilation is improved *Respiratory depressant drugs, such as morphine, and even the barbiturates, should be avoided* Relief of the hypercapnia may restore the sensitivity of the respiratory center to the carbon dioxide stimulus Relief of the hypoxemia takes much of the burden off the heart Oxygen may be used but with care not to depress respiration and increase carbon dioxide retention Mechanical respiratory aids, such as the intermittent positive-pressure breathing devices, are therefore often necessary An intercurrent acute bronchitis may be a major catastrophe for these patients, often abruptly causing severe hypoxemia, hypercapnia, and right heart failure At this time, not only should antibiotics and bronchodilators be used, but a tank respirator may be necessary

Treatment of Chronic Cor Pulmonale Due to Predominant Involvement of the Pulmonary Vessels. Therapy of chronic cor pulmonale in patients with pulmonary disease in whom the disease tends to be localized in or about the pulmonary vessels is unsatisfactory. When bronchopulmonary infection or chronic obstructive emphysema is present as a complication, it should be treated intensively. The latter especially may complicate such conditions as silicosis and diffuse pulmonary sarcoidosis. Harvey and associates (1953) have advised continuous marked restriction of physical activity in these patients as one of the few procedures which can be employed to reduce the strain on the right heart, since the pulmonary vascular bed is restricted in a permanent anatomic manner. In multiple recurrent small pulmonary emboli, thrombosis of the major pulmonary arteries, and probably *primary pulmonary hypertension*, *continuous anticoagulant therapy* should be used. *Priscoline* and the *ganglionic blocking agents* have been disappointing In these conditions, also, the pulmonary vascular bed is so restricted that great caution must be used in the administration of intravenous fluids, the injection of small *amounts of fluid* has been reported to cause *cyanosis*, collapse, and death (Cross and Kobayashi, 1947). When the essential functional abnormality is alveolar-capillary block without hypercapnia, *oxygen* in high concentrations *may* be given When there is interstitial infiltration with granulomas which will respond to specific medication, such as the *adrenal corticosteroids*, such medication should be employed. However, it is usually impossible to predict whether resolution or fibrosis of these granulomas will occur

1955), their clinical usefulness in the treatment of the hypercapnia of patients with pulmonary insufficiency has not been demonstrated. Furthermore, in patients with chronic diffuse obstructive emphysema, the stimulation of respiration may be disadvantageous if the work of breathing is increased beyond a critical level, so that the augmented work of the respiratory muscles increases carbon dioxide production beyond the capacity of the lungs to eliminate it (Otis, 1954; Riley, 1954; Bader and Bader, 1955) Far more rational is therapy directed at reducing the work of breathing by methods listed above or by the use of a mechanical respirator.

Patients with chronic cor pulmonale in congestive failure and respiratory acidosis are critically ill. They are often difficult to manage As a result of hypoxia and hypercapnia, they are frequently somnolent, confused, and combative Cerebrospinal fluid pressure is often increased, even to the extent of producing papilledema (Mithoefer, 1952, Patterson et al., 1952) Restoration of alertness is of prime importance, since it will permit more effective coughing and expectoration of sputum and greater cooperation with therapeutic procedures.

Cardiac therapy will be effective only if combined with the above pulmonary measures *Digitalis*, contrary to earlier reports, has been shown to definitely improve cardiac performance in patients with chronic cor pulmonale and congestive failure (Ferrer et al, 1950), and is therefore indicated *Mercurial diuretics* and *salt restriction* should also be employed, with attempts to avoid electrolyte imbalance Initially, *bed rest* is extremely important to reduce the body's metabolic requirements; the arterial blood oxygen saturation in these patients falls markedly with exercise. Yet immobilization favors shallow breathing and retention of bronchial secretions *Phlebotomy* becomes important in the presence of polycythemia The possible advantages and disadvantages of polycythemia and of the associated hypervolemia have been discussed above. Since the red blood cells in secondary polycythemia are often hypochromic, consideration should be given to the hemoglobin as well as to the red blood cell counts and hematocrit. Bleeding is advisable when the hematocrit is above 55; 300 to 500 cm^3 of blood may be removed every 3 to 5 days to bring the hematocrit down to 50, and the hemoglobin to about 14 Gm Since many of these patients have associated arteriosclerotic or hypertensive heart disease, the presence of some degree of left ventricular failure, due to these associated conditions, will often result in a particularly gratifying response to specific cardiac therapy.

Surgical excision of localized giant bullae has been performed in patients with severe emphysema and cor pulmonale Clinical benefit was seen in those patients who had already developed resting hypoxia and right heart failure (Fitzpatrick et al., 1957). *Thyroid ablation* by large doses of radioactive iodine has been used to lower the basal oxygen requirements of the body tissues in some very severe cases of diffuse obstructive emphysema. Significant improvement in some patients has been reported (Bercu and Mandell, 1954, Hurst et al., 1955).

Peptic ulcer has been noted to occur with much greater frequency in patients with chronic obstructive emphysema than in the general population (Fulton et al., 1952, Weber and Gregg, 1955; Mack and Snider, 1956). Barium studies of the upper gastrointestinal tract should therefore be performed routinely, they are particularly important if corticotropin or adrenal corticosteroid therapy is to be employed, since these drugs notoriously cause reactivation of peptic ulcer

Prophylactic therapy in patients with chronic diffuse obstructive emphysema is of the utmost importance They should be examined at regular intervals and advised to report immediately any of the following danger signals acute respiratory tract infection, fever or malaise, purulent sputum, hemoptysis, and chest pain They should know the purpose of each of their medicaments Chronic bronchitis must be attacked vigorously, not only by a studied medical regime but also by corrective manipulation of the environment. This includes attention to industrial safeguards, air pollution, poverty, and health education. *Smoking should be forbidden.* In patients with diffuse obstructive emphysema, acute respiratory infections should be treated as major illnesses. Not only may their effects be cumulative and lasting, but with signs of increasing pulmonary dysfunction, polycythemia, and blood gas abnormali-

ties, they frequently herald impending pulmonary and circulatory breakdown. These may be prevented by intense therapy. While the acute respiratory infection which often initiates a downhill course in these patients is usually originally of viral origin, it is the bacterial superinfection which lingers and is eventually the most disturbing. For this reason, in those patients in whom repeated respiratory infections occur, the use of small doses of broad-spectrum antibiotics, daily or several times weekly, especially during the winter, may be very valuable (McVay and Sprunt, 1953). It is often advisable to interrupt such prophylactic treatment periods to permit the reestablishment of normal saprophytic flora.

Treatment of Chronic Cor Pulmonale Due to Chronic Alveolar Hypoventilation Syndromes. In this group of conditions, treatment of right heart failure includes the usual cardiac measures and phlebotomy. However, no success will be achieved unless alveolar ventilation is improved. *Respiratory depressant drugs, such as morphine, and even the barbiturates, should be avoided.* Relief of the hypercapnia may restore the sensitivity of the respiratory center to the carbon dioxide stimulus. Relief of the hypoxemia takes much of the burden off the heart. Oxygen may be used but with care not to depress respiration and increase carbon dioxide retention. Mechanical respiratory aids, such as the intermittent positive-pressure breathing devices, are *therefore* often necessary. An intercurrent acute bronchitis may be a major catastrophe for these patients, often abruptly causing severe hypoxemia, hypercapnia, and right heart failure. At this *time*, not only should antibiotics and bronchodilators be used, but a tank respirator may be necessary.

Treatment of Chronic Cor Pulmonale Due to Predominant Involvement of the Pulmonary Vessels. Therapy of chronic cor pulmonale in patients with pulmonary disease in whom the disease tends to be localized in or about the pulmonary vessels is unsatisfactory. When bronchopulmonary infection or chronic obstructive emphysema is present as a complication, it should be treated intensively. The latter especially may complicate such conditions as silicosis and diffuse pulmonary sarcoidosis. Harvey and associates (1953) have advised continuous marked restriction of physical activity in these patients as one of the few procedures which can be employed to reduce the strain on the right heart, since the pulmonary vascular bed is restricted in a permanent anatomic manner. In multiple recurrent small pulmonary emboli, thrombosis of the major pulmonary arteries, and probably primary pulmonary hypertension, *continuous anticoagulant therapy* should be used. *Priscoline* and the *ganglionic blocking agents* have been disappointing. In these conditions, also, the pulmonary vascular bed is so *restricted* that great caution *must* be used in the administration of intravenous fluids; the injection of small *amounts of fluid* has been reported *to* cause cyanosis, collapse, and death (*Cross* and Kobayashi, 1947). When the essential functional abnormality is alveolar-capillary block without hypercapnia, *oxygen* in high concentrations *may* be given. When there is interstitial infil-*tration with* granulomas which will respond to specific *medication*, such as the *adrenal* [illegible] ...osis of these granulomas will occur.

The blood in cor pulmonale

MARIO STEFANINI AND STEPHEN C. MATHEWSON

The subject of this chapter finds its practical importance in the increasing occurrence of cor pulmonale. An autopsy survey in an area in the United States has shown 6 3 per cent cases of cor pulmonale due to pulmonary emphysema in 790 cases with heart disease (Scott and Garvin). In an industrial area in England, among 300 patients, cor pulmonale was found responsible for congestive heart failure in 8 5 per cent of the females and 40.5 per cent of the males (Flint). These figures justify the statement by many cardiologists that *cor pulmonale represents today the fourth most common disease of the circulatory system*, following rheumatic, coronary, and hypertensive heart disease.

For the purpose of this discussion, cor pulmonale is defined as the right ventricular hypertrophy which develops as result *of increased* resistance to the flow of blood through the pulmonary circulation, because of pathologic conditions in the lungs or in the pulmonary vessels. This definition excludes enlargement of the right ventricle due to any other cause, such as left ventricular failure and congenital or acquired diseases of the myocardium, endocardium, or pericardium Cor pulmonale (see classification, Causes of Chronic Cor Pulmonale, in Chap 8) may be *acute* (as it occurs in massive pulmonary embolism), *subacute* (as it may be occasionally seen in metastatic carcinoma or lymphoma of the lung with fine parenchymal dissemination), or *chronic* Chronic cor pulmonale may be produced by two essential mechanisms: (1) *chronic obstructive emphysema;* (2) *chronic disease of the pulmonary arterial vessels.* This discussion will be limited to chronic cor pulmonale, as this has the most profound effects on the bone marrow and on the blood.

The mechanism of production of chronic cor pulmonale also deserves some discussion, as it has important bearing on the intensity and frequency of blood complications. Whatever the cause, the cross-sectional diameter of the pulmonary bed is reduced at first, and the capacity of the small pulmonary vessels to distend is consequently diminished. In the emphysematous type, external compression of the capillaries by bullae, and shrinkage and distortion of the vascular bed because of pericapillary exudation, necrosis, and scarring, are the most important mechanisms In the predominantly vascular type, endoarterial diseases, such as embolization and arteritis, *primary* pulmonary hypertension, or involvement of the interstitial tissue, are all important. The loss of cross-sectional area leads to increased resistance to the flow of blood through the pulmonary vessels and to *hypoxia* (quite rapidly in the emphysematous type, much later in the vascular type of cor pulmonale). Also, the increased resistance to blood flow through the lung causes prompt elevation of the right heart output As the volume of venous return to the heart increases, there is an additional burden on the right ventricle A vicious circle is established, with ever-increasing hypoxia.

THE BLOOD AND BONE MARROW

The present section will be limited to a general discussion of the fundamental aspects

of the hematologic abnormalities in cor pulmonale *It may be stated that, in general, significant hematologic changes in cor pulmonale occur only after decompensation and heart failure have set in.* The central mechanism, as in congestive heart failure, is *hypoxia* The reasons why hypoxia leads to changes in blood, plasma proteins, serum electrolytes, etc., are similar to those which apply in congestive heart failure and in congenital cyanotic heart disease Yet, blood changes seen in cor pulmonale are usually more pronounced than those seen in congestive heart failure, *because of the combined features of primary hypoxia and heart failure.*

Red cell count, hematocrit, hemoglobin, and reticulocytes are remarkably increased. In fact, hematocrit values of 60 per cent or more are not uncommon. As the hematocrit rises, the blood viscosity also increases and the blood sedimentation rate drops (especially if there is concomitant fibrinogenopenia) On the other hand, white cell and platelet counts are usually normal[1] The bone marrow reflects the increased erythropoietic activity with marked hyperplasia of the erythroid elements Isotopic studies indicate an accelerated iron turnover and considerable increase in red cell mass With high red cell mass, blood volume is usually high Plasma volume is, at least *in the beginning, normal* Later, however, as decompensation sets in, *hypervolemia* may develop because of increased volume of circulating plasma and of interstitial and, possibly, *intracellular* fluid owing to kidney involvement and retention of sodium, a situation which will be discussed in the chapter on congestive heart failure (see Part 18) *In general,* plasma volumes are higher *in* patients with cor pulmonale following *correction* of congestive failure and polycythemia (Lewis et al , 1954), and both blood and plasma volumes fall after successful digitalization (Ferrer et al , 1950)

[1] Occasionally, leucocytosis, neutrophilia, and thrombocytosis may be found in patients who have become cyanotic and acidotic because of cor pulmonale The underlying primary disease may cause elevation of serum carbon [illegible]

[illegible]

PLASMA PROTEINS

Changes seen in the protein composition of plasma are, in general, similar to those which accompany congestive heart failure.

BLOOD GASES AND ELECTROLYTES

Analysis of blood gases and serum electrolytes in patients with cor pulmonale reveals the changes due to pulmonary dysfunction and *circulatory* impairment. Arterial oxygen saturation and oxygen tension are lower than normal. The oxygen saturation is generally of 70 per cent or less, a situation known to lead to *polycythemia.* There is higher than normal arteriovenous oxygen gradient in these patients while at rest, which increases during exercise. Also, with severe pulmonary disease, *the carbon* dioxide retention may be marked, and respiratory acidosis may be seen. Under these circumstances, *the serum* chloride level *is reduced.*

Renal plasma flow and glomerular filtration rate are decreased, as they *generally* are in congestive heart failure, but only if *congestive* heart failure or polycythemia is present. Retention of sodium then occurs, with all the consequences already described *in Part 18.*

HEMORRHAGIC AND THROMBOTIC COMPLICATIONS

In general, the incidence of hemorrhagic and thrombotic complications in cor pulmonale *seems* lower than in congestive heart failure. The authors have seldom *seen* a case of cor *pulmonale* complicated by truly severe hemorrhagic manifestations, even following emergency surgery. The incidence of *thrombosis* is, on the other hand, higher. Although no statistical figures are available, phlebothrombosis of the deep leg veins is *not uncommon* in cor pulmonale, at least *in* the authors' experience Many of the pathogenetic factors are those of *congestive* heart failure, including *the* fact that most patients with cor pulmonale are in the age group in which phlebothrombosis is most frequent. Also, the disease is debilitating and forces the patients to a great deal *of rest,* which deprives them of the stimulus *to* venous return represented by the muscular contraction Additional factors are particular to cor pulmonale Hunter et al. have rightly emphasized the importance *of normal* negative

intrathoracic and abdominal pressures to prevent phlebothrombosis. In emphysema, intrapleural negative pressure is decreased, and this, in turn, delays the venous return to the right side of the heart. Also, prolonged expirations and poor thoracic excursions do not encourage proper venous return. Methods of therapy, such as pneumoperitoneum and abdominal binders, enhance the stasis in the lower extremities. In addition, hypoxemia produces venous endothelial damage, which, in turn, encourages clot formation (McLachlin and Paterson). Finally, when severe decompensation exists, other factors, such as the prolongation of the circulation time and the occurrence of venous stasis, may lead to phlebothrombosis.

As will be described in congestive heart failure, *intravascular clotting probably occurs continuously in these patients during life.* In fact, occasional evidence of silent premortal intravascular clotting is found at autopsy in patients with cor pulmonale. Expression of continuous intravascular clotting may also be the moderate thrombocytopenia and fibrinogenopenia, the decreased activity of labile factor, and the mild activation of the fibrinolytic system which are occasionally found in these patients.

Clinical experience seems to indicate that patients with cor pulmonale are especially prone to thrombotic accidents in the wake of surgery. The prevention of this complication is best achieved by venesection, to reduce as much as possible the hematocrit value without aggravating the hypoxia.

1

Acute and chronic hypotension

LOUIS F. BISHOP AND JEROME NOBLE

Hypotension connotes a level of blood pressure below that which is considered normal. It becomes obvious, immediately, that this normal level must be defined before a blood pressure reading may be regarded as "low" Furthermore, it is generally agreed that a variation in blood pressure below any statistically accepted norm is not necessarily associated with complaints on the part of the patient The mere objective finding of "low" blood pressure by the examining physician in the absence of subjective complaints or other positive physical findings may be regarded as of no clinical significance Occasionally, the physician may unwittingly cause unjustifiable concern in his patient by relating this finding during the course of an office consultation (*iatrogenic hypotension*).

For the purpose of clarity and understanding, an attempt was made to classify the various hypotensive categories in the following outline (Scott, R W, et al)

I. Essential hypotension (not associated with any demonstrable disease state)
   A. Asymptomatic
   B. Constitutional
II Secondary hypotension
   A. Acute secondary hypotensive states
      1. Shock
         a Metabolic
         b Surgical
         c Traumatic
         d Cardiogenic
         e Miscellaneous, medical
      2. Carotid sinus syndrome
      3. Acute infectious diseases
      4 Hypotensive drugs and anesthetics
      5. Hysteria
      6. Cough syncope
      7. Effort syncope due to primary pulmonary hypertension
      8 Hypoxia
      9 Strenuous exercise
      10. Chronic valvular disease of the heart
      11. Hypotension in aviation
      12 Heat exhaustion and heat stroke
   B. Chronic hypotension
      1. Primary idiopathic orthostatic hypotension
      2 Secondary—chronic orthostatic hypotension as a result of
         a Sympathectomy (postsympathectomy syndrome)
         b Central nervous system disorders
         c Chronic debilitating diseases
      3 Endocrinopathies
      4. Chronic cardiac disorders

ESSENTIAL HYPOTENSION

Asymptomatic. This group includes persons who present themselves to the physician for a routine checkup or are examined by physicians for insurability. In these cases, the patient or applicant for insurance is completely symptom-free, and hypotension is merely an incidental finding.

Statistically, the incidence of hypotension is practically unknown Insurance companies know that "the *mortality* rate among persons with blood pressures below the average is significantly lower than that among persons with so-called 'normal blood-pressure.'" As for *morbidity*, one insurance company will refuse a policy if the applicant's pressure is "more than 40 mm below average." However, for the most part, it is thought that "low blood pressure, in the absence of accompanying disorders, is not regarded as of much import."

Another insurance company feels that "hypotension never kills, only fills the mind with anxiety; usually not charged an extra premium. If diastolic pressure is below 60, there is a strong possibility of aortic regurgitation" (personal communications).

The earlier literature did not consider hypotension to be of significance (Bishop, 1904; Faught, 1913, Norris et al., 1927). A resurgence of interest in the subject is indicated in more recent European literature (Gallavardin, 1945; Lassance, 1954) and in the current abstracting and indexing compilation of the periodicals

As mentioned above, a symptom-free individual, whose physical findings are completely within normal limits except for hypotension, cannot be regarded as hypotensive until a normal range of blood pressure is established As may be anticipated, there are many factors to be considered in establishing this norm Blood pressure values vary from race to race, Eastern Asiatics, for example, show lower readings in all age groups than do Europeans or Americans. Pressures vary in accordance with sex Women between puberty and menopause on an average have lower pressures than men of corresponding age After the menopause, however, females have higher average blood pressures than males in similar age groups In a large sampling of apparently healthy men and women of ages ranging from 65 to 106 years (Master et al.), the "mean blood pressure was 145/82 for men and 156/84 for women." After the age of 74, the systolic pressure declines slowly in women and remains constant in men The mean diastolic pressure shows little variation from the ages of 65 to 80 and tends to decline thereafter

According to one representative insurance group, the following are the *minimal* normal pressures in accordance with ages.

Ages	*Systolic*	*Diastolic*
10–19	90	50
20–39	100	55
40–up	110	60

Finally, in summing up the viewpoint of another insurance group appraising hypotension, "hypotension is not a disease but an anomaly. Its deviation below average may or may not be abnormal Moderate hypotension, say down to 100 mm systolic, is compatible with good health; down to 90 mm, in many instances even down to 80 mm, abnormality may not be assumed . . . not a few persons with 90/60 readings are in excellent health" (personal communications).

Constitutional Type. This category of hypotensive persons includes those who have symptoms that may be related to their blood pressures. Some have *poor work capacity, poor resistance* to physical strain, and extreme sensitivity to weather changes They may be inefficient, easily fatigued industrial workers, poor soldiers, etc. They are not debilitated or malnourished and have no laboratory or clinical stigmata of organic disease states. They may, however, complain of *headaches, dizziness,* and easy *fatigability* They may show poor muscular development and may be of sedentary habit. As a constitutional type, they are frequently of the asthenic habitus Although their prognosis as to longevity is excellent, they may be *poor surgical risks,* and also may be more prone to severe *occlusive complications* with the onset of advancing arteriosclerotic blood vessel changes.

Evidence has been presented indicating the existence of an association between body builds and blood pressures by comparative statistical investigative studies (Weiss, A.). One thousand hypertensive persons, 1,000 normotensive persons, and 1,000 hypotensive persons were selected at random from 100,000 men ranging in age from 56 to 60 They were subjected to body-measurement studies (somatometry). The results were compared and statistically analyzed No correlation was found between height and blood pressure However, an unequivocal correlation existed between the circumference of the thorax and the blood pressure Respiratory excursions were greatest in the normotensive and smallest in the hypertensive groups The height-width index (body height/average thoracic circumference) was greater in hypotensive persons and showed decreases in hypertensive persons, while the reciprocally proportional thoracic circumference increased in going from the hypotensive to the hypertensive groups. Body weight showed an evident increase with increasing blood pressure The height-weight index (body height in centimeters over 100 cm/body weight in kilograms) decreased with an increase in blood pressure

As summarized, the data indicated that *the thin, small-chested individual (asthenic) is statistically most commonly the constitutionally hypotensive individual*

Hypotension and its implications have received more attention in the foreign literature than in that of the United States. A syndrome in which hypotension not associated with other symptoms or signs other than lassitude, decreased fitness, empty feeling in the head, and a tendency toward dizziness and bouts of sweating occurring in the morning has been reported (Svartz). It is considered an isolated sign, which responds to treatment and tends to improve as the day progresses, the blood pressure generally increasing towards evening.

"Acquired permanent hypotension" and its effect upon work efficiency is a subject of considerable investigation in other countries. The effect of hypotension upon industrial workers has been the subject of recent studies carried out in Italy (Piazza et al; Bonsangue). Initially, Ferrannini (1903) commented upon primary hypotensive states Subsequently Bishop (1904), Hertz, Muenzer, Goodman, Martinet, and others considered the syndrome of permanent idiopathic arterial hypotension. Pal, Bard, Gallavardin, Herz, Alvarez, Borach, Yoachim, Munk, and later Friedlander, Luisada (1929), Kisch, and still others studied the etiology and pathogenesis of this condition Pellegrini (1952) studied this syndrome further after perusing the literature and decided that it was secondary to a deficiency in arterial and arteriolar tone The problem, however, remained unsolved and was generally referred to as "idiopathic," in so far as mechanism and physiology were concerned

Following World War II, this syndrome has become increasingly prevalent The condition was studied in working classes It was found that certain electrical workers developed weakness and dizziness upon climbing ladders

These workers were found to have an average diastolic blood pressure of 100 mm. The phenomenon was studied more intensively in 400 workers, aged 18 to 40 They were found to be normal psychiatrically and organically Of this group, 192 were considered hypotensive. It should be noted that these investigators considered 115 mm Hg to be the lower limits of normal The following blood pressures were found 37 per cent, 115 mm, 31.70 per cent, 110 mm, 13 54 per cent, 105 mm, 11 95 per cent, 100 mm; 3 12 per cent, 95 mm, and 1.56 per cent had blood pressures of 90 mm. These persons had been observed for many years prior to the time of this study, and documentary proof in each case indicated that their blood pressures had been above 115 mm *in the past.*

It was considered that the present hypotension was an acquired state secondary to unknown factors which had resulted from innate individual mechanisms. It was finally concluded that this phenomenon represented poor cardiovascular tone. An additional 200 subjects were selected at random in a subsequent study, and it was found that 114 of these, likewise, had blood pressures of 115 mm or less. They had been observed for 3 to 11 years, and there was clinical documentation regarding their physical status and their subjective complaints. It was concluded that persons suffering from "acquired idiopathic permanent hypotension" may be potentially poor work risks in hazardous occupations; *e.g.*, if they are electrical workers they tend to suffer dizziness while climbing ladders.

Physiologic Mechanisms in Essential Hypotension. The physiologic mechanisms which result in the physical finding of hypotension reflect the summation of homeostatic processes constantly in operation, such as cardiac output, the tonus of the peripheral vascular bed, and the oxygen requirement of the body as a whole The resultant of these is reflected in the blood pressure readings, which vary from individual to individual depending upon the degree to which each factor may be operative. Those asymptomatic individuals whose resultant hypothetic "*sphygmostat*" (blood pressure regulator) is set *at a low level* may be regarded as *normal variants*, while those whose low "sphygmostatic" level is productive of symptoms, may be regarded as a constitutionally *abnormal type* The basic explanation, however, remains unknown

SECONDARY HYPOTENSION

This group is extremely heterogeneous, since hypotension is merely a sign, only one part of a *syndrome*, symptom complex, or disease entity Hypotension in this connection is merely secondary to mechanisms resulting in the genesis of the syndrome For example, the hypotension that accompanies shock is an integral part of that syndrome but gives no indication as to the mechanism or etiologic factors which may have produced it.

Acute Secondary Hypotensive State. This term refers to a sudden precipitous fall in blood

pressure frequently associated with syncope or semicomatose, shock, or shocklike states. The condition may be quickly reversible or lingering. There are many syndromes of which acute hypotension is a part.

Shock. Shock is an example of an acute hypotensive state. There are several categories of shock or shocklike states, including surgical, traumatic, metabolic, and cardiogenic.

It is interesting to note the frequency of occurrence of postoperative adrenal cortical insufficiency. "One out of 300 patients subjected to surgery exhibit some form of adrenal cortical insufficiency." Cases are reported of acute adrenal cortical insufficiency in which persistent hypotension and shocklike states develop during surgery and immediately postoperatively, with severe peripheral collapse and failure to respond to intravenously administered blood and serum, electrolyte therapy, and vasoconstrictors. These patients, however, respond promptly to intravenous hydrocortisone therapy. The mechanism whereby hydrocortisone produces such prompt therapeutic response is not known. It is thought to be the result of the potentiating effect upon vasoconstrictor agents or the direct effect upon the peripheral blood vessels (Adams et al.)

Cardiogenic Shock. The mechanism and classification of *cardiogenic shock* in the following paragraphs are largely taken from reviews of this subject (Sampson).

The figure 10 per cent is generally quoted to be the incidence of shock accompanying all cases of *myocardial infarction.* Vasopressor drugs have been credited with reducing the mortality in those shock patients if treatment is instituted within 3 hr (Griffith et al).

"Cardiogenic shock" (shock of cardiac origin) is characterized by an acute precipitous fall in the blood pressure and by signs of acute circulatory collapse, viz., weak rapid pulse, pallor or cyanosis, sweating, anxiousness, and restlessness. Hypotensive episodes such as these are due primarily to myocardial failure to maintain adequate blood flow Concomitantly, there is peripheral vascular failure The mechanism in myocardial infarction, the most common cause of cardiogenic shock, is primarily *a sudden reduction in left ventricular output due to a direct loss of functioning myocardium* Secondarily, there is *an autonomic reflex causing pooling of the blood in the viscera and dependent portions of the body* (Sampson)

Following extensive myocardial infarction, there is *a reduction in stroke volume,* which may result in congestive heart failure and accentuation of the shocklike state Vasoconstrictor mechanisms (arterial) fail to maintain normal blood pressure, and the reduced "head of pressure" is insufficient to supply the myocardium, brain, and kidneys with adequate oxygen.

Some significant data have resulted from the production of shock experimentally in dogs, which if applicable to human beings, help explain the pathophysiology of shock accompanying myocardial infarction (Corday et al). It has been shown that following experimental shock there is reduced coronary blood flow. Furthermore, the ballooning of the ischemic myocardium following ligation of the coronary arteries seems to become exaggerated when the blood pressure is lowered by bleeding In order to maintain adequate oxygen supply to the myocardium and to prevent irreversible myocardial damage, the pressure within the coronary arteries must be maintained at adequate levels. The rapid restoration and maintenance of the systemic blood pressures sufficient to provide adequate coronary artery blood pressure levels is one goal in the treatment of shock that may accompany acute myocardial infarction.

In addition to the above-mentioned *myocardial hypoxia* resulting from acute hypotension of cardiogenic shock, *cerebral hypoxia* may be a factor in the ultimate prognosis of patients having cerebral as well as coronary arteriosclerosis. The effect of artificially induced hypotension upon the cerebral hemodynamics of 12 individuals over 50 years of age with evidence of cerebral vascular disease and hypertension has been studied using tetraethylammonium chloride (Bessman et al.).

No quantitative changes were noted in the cerebral hemodynamics, but 80 per cent of the patients manifested subjective and objective signs ordinarily attributed to cerebral anoxia during the period of hypotension. This apparent discrepancy was explained by vasodilatation occurring in less diseased vessels at the expense of the severely arteriosclerotic vessels and producing a "stagnant anoxia" not measurable by current techniques The hypoxia thus would occur in those areas which had a barely adequate oxygen supply prior to the time hypotension

If the shock persists, *irreversible shock* ensues The duration of this interval before irreversible shock develops may be from 1 to 4 hr. Small-vessel thromboses, especially in the lungs, as a result of "hypercoagulability and stagnant flow" or/and the release of some vasodepressor substance (VDM) coming from hypoxic liver tissue (Shorr et al) may explain irreversible shock. The addition of heparin to vasopressor infusions has been reported to improve the survival rate (Griffith)

Cardiac conditions other than myocardial infarction may produce cardiogenic shock and be associated with sudden reduction in cardiac output, they are cardiac tamponade (traumatic or ruptured dissecting aneurysm) and supraventricular or ventricular tachycardia. Ventricular fibrillation caused by electric shock results in sudden fall in cardiac output and sudden death. Acute myocarditis, Stokes-Adams syndrome, ventricular standstill, ball-valve thrombus, or pedunculated myxomas may cause shocklike states with acute hypotensive episodes, as a result of ventricular asystoles or ineffective ventricular contractions

Miscellaneous Medical Entities. The following entities may produce *shocklike* states and occasionally result in myocardial infarction and cardiac decompensation·

1 *Hemorrhage* due to gastrointestinal bleeding, e g , bleeding peptic ulcer
2. *Reduction in circulating blood volume* due to dehydration, vomiting, or diarrhea with associated sodium and potassium imbalance
3 *Cerebral accidents*—occlusion of cerebral arteries or hemorrhage
4 *Pulmonary embolism* and infarction
5 *Peripheral vascular collapse as a result of*
   a Anaphylaxis or anaphylactoid reactions resulting from allergies to horse *serum or egg* albumin, and in *favism* (the liberation of histamine produces *arteriolar* dilatation with loss of fluid into the interstitial tissues as a result of increased capillary permeability with consequent reduction in the circulating blood volume)
   b. Gram-negative bacterial septicemias
   c. Parenteral drug sensitivities (penicillin, histamine, mercury, arsenic, aminophylline, barbiturates, Pronestyl, quinidine, veratrum, or chlorpromazine)
   d Acute adrenal insufficiency resulting from meningococcemia (Waterhouse-Fridrichsen syndrome)

[illegible]

An acute drop in arterial blood pressure levels may result from a *hypersensitive carotid sinus.* Basically, the hypotension results from vagal stimulation such as occurs in pressure on the eyeball (oculovagal reflex), paracentesis (peritoneal reflex), and thoracentesis [illegible]vagal reflex). The results are slowing [illegible] and [illegible] cerebral hypoxia. Treatment [illegible]ninistration of *atropine* by mouth, 05 mg three times a day, in order to cause paralysis of the vagal nerve endings

Acute Infectious Diseases. Cholera, diphtheria, pneumonia, scarlet fever, typhoid, typhus, and epidemic hemorrhagic fever have caused acute hypotensive episodes which may persist for long intervals Particularly, gram-negative *bacteremias* and other *acute fulminating infections* may result in severe hypotensive states secondary to peripheral vascular collapse. Blood or plasma transfusions are of little value in their treatment, since there is no evidence of hemoconcentration or decreased blood volume It is thought that the peripheral vasodilatation resulting from a decrease in peripheral vascular tone is secondary to depression of vasomotor *centers* in the central nervous system In addition to peripheral vascular failure, acute toxic myocarditis (streptococcal infections, acute glomerulonephritis, acute rheumatic fever, or diphtheria) may complicate the picture, leading to severe shock and death In *typhus fever*, characteristically, the patients suffer severe hypotensive periods followed by renal insufficiency with accompanying diminished urea clearance, increase of blood urea nitrogen, and oliguria. In *epidemic hemorrhagic fever* (*Manchurian fever*)—a disease thought to be due to a virus—fever, prostration, vomiting, proteinuria, and shock with renal failure may develop

The disease attracted wide attention during the Korean War in 1951 among United Nations troops Early death due to shock, generally associated with retroperitoneal hemorrhage and petechiae in the viscera, occurred in 13 cases. The hypotensive *phase* was associated with reduced blood volume and marked elevation in the hematocrit, presumably due to loss of plasma into the tissue [illegible]

pressure frequently associated with syncope or semicomatose, shock, or shocklike states. The condition may be quickly reversible or lingering. There are many syndromes of which acute hypotension is a part.

Shock. *Shock* is an example of an acute hypotensive state. There are several categories of shock or shocklike states, including surgical, traumatic, metabolic, and cardiogenic.

It is interesting to note the frequency of occurrence of postoperative adrenal cortical insufficiency. "One out of 300 patients subjected to surgery exhibit some form of adrenal cortical insufficiency." Ventricular fibrillation caused by electric shock results in sudden fall in cardiac output and sudden death Acute myocarditis, Stokes-Adams syndrome, ventricular standstill, ball-valve thrombus, or pedunculated myxomas may cause shocklike states with acute hypotensive episodes, as a result of ventricular asystoles or ineffective ventricular contractions

Miscellaneous Medical Entities. The following entities may produce shocklike states and occasionally result in myocardial infarction and cardiac decompensation.

1. *Hemorrhage* due to gastrointestinal bleeding, e g , bleeding peptic ulcer
2. *Reduction in circulating blood volume* due to dehydration, vomiting, or diarrhea with associated sodium and potassium imbalance
3. *Cerebral accidents*—occlusion of cerebral arteries or hemorrhage
4. *Pulmonary embolism* and infarction
5. *Peripheral vascular* collapse as a result of
   a. *Anaphylaxis* or anaphylactoid reactions resulting from allergies to horse serum or egg albumin, and in *favism* (the liberation of histamine produces arteriolar dilatation with loss of fluid into the interstitial tissues as a result of *increased* capillary permeability with consequent reduction in the circulating blood volume)
   b. *Gram-negative* bacterial septicemias
   c. *Parenteral drug sensitivities* (penicillin, histamine, mercury, arsenic, aminophylline, barbiturates, Pronestyl, quinidine, veratrum, or chlorpromazine)
   d. *Acute adrenal insufficiency* resulting from meningococcemia (Waterhouse-Friderichsen syndrome)
   e. *Epinephrine and l-norepinephrine* deficiencies following removal of adrenal tumors

An acute drop in arterial blood pressure levels may result from *a hypersensitive carotid sinus.* Basically, the hypotension results from vagal stimulation such as occurs in pressure on the eyeball (oculovagal reflex), paracentesis (peritoneal reflex), and thoracentesis (pleurovagal reflex). The results are slowing of the heart rate, reduced cardiac output, and peripheral vasodilatation with consequent cerebral hypoxia. Treatment consists of administration of *atropine* by mouth, 0 5 mg three times a day, in order to cause paralysis of the vagal nerve endings.

Acute Infectious Diseases. Cholera, diphtheria, pneumonia, scarlet fever, typhoid, typhus, and epidemic hemorrhagic fever have caused acute hypotensive episodes which may persist for long intervals Particularly, gram-negative *bacteremias* and other *acute fulminating infections* may result in severe hypotensive states secondary to peripheral vascular collapse Blood or plasma *transfusions* are of little value in their treatment, since there is no evidence of hemoconcentration or decreased blood volume It is thought that the peripheral vasodilatation resulting from a decrease in peripheral vascular tone is secondary to depression of vasomotor centers in the central nervous system. In addition to peripheral vascular failure, acute toxic myocarditis (streptococcal infections, acute glomerulonephritis, acute rheumatic fever, or diphtheria) may complicate the picture, leading to *severe shock* and death In *typhus fever*, characteristically, the patients suffer severe hypotensive periods followed by renal insufficiency with accompanying diminished urea clearance, increase of blood urea nitrogen, and oliguria In *epidemic hemorrhagic fever* (*Manchurian fever*)—a disease thought to be due to a *virus*—fever, prostration, vomiting, proteinuria, and shock with renal failure may develop

The disease attracted wide attention during the Korean War in 1951 among United Nations troops. Early death due to shock, generally associated with retroperitoneal *hemorrhage* and petechiae in the viscera, occurred in 13 cases The hypotensive phase was associated with reduced blood volume and marked elevation in the hematocrit, presumably due to loss of plasma into the tissue spa-

The *treatment* is general and supportive, and specific therapy is employed depending upon the etiologic agent. Digitalis is indicated in severe cardiac decompensation; intravenous l-norepinephrine is used to combat the severe peripheral vascular dilatation.

Hypotensive Drugs and Anesthetics. Drugs used in the treatment of hypotension may cause acute hypotensive episodes with syncope.

Ganglionic blocking agents (tetraethylammonium chloride and hexamethonium) may result in acute postural hypotension with tachycardia. The ganglionic blockade causes decreased peripheral arterial resistance.

Centrally acting *sympatholytic agents* (1-hydrazinophthalazine–*Apresoline*) may likewise cause pooling of the blood and venous congestion in dependent portions of the body associated with loss of tone in the peripheral vascular bed and consequent hypotension and syncope.

Relatively severe acute hypotensive episodes may occur with the use of *spinal anesthesia*, deep inhalation anesthesia, and tribromoethanol (*Avertin*).

Hysteria. Severe emotional reactions may result in an acute hypotensive episode with *syncope*. This generally occurs in individuals with marked vasomotor instability. Horror at witnessing a gruesome spectacle, news of sudden death, the sight of blood, fear of venipuncture, and the marked vasodepression when sensitive organs are injured (testicles, incising a boil, inserting a canula into an artery, stimulating sciatic or ulnar nerves) may precipitate fainting. In anticipation of the threatened "faint," one notes marked pallor, anxiousness, sweating, weakness, and nausea. The blood pressure falls acutely and is associated with tachycardia. Particularly in the upright position, there is pooling of the blood in the lower extremities, secondary to reflex muscular vasodilatation There is reduced cerebral blood flow with consequent cerebral hypoxia, and syncope ensues Treatment consists of lying down or bending the head and trunk and drawing up the knees.

Cough Syncope and Reduced Venous Return to the Heart. Severe paroxysms of cough cause a rise in the intrathoracic pressure, which reduces the venous return (Valsalva maneuver), thus reducing cardiac output and consequently lowering the blood pressure, with attendant syncope and, occasionally, convulsi[ve] seizures. Treatment is directed against increa[s]ing the intrathoracic pressure by avoiding li[ft]ing or pushing heavy objects or straining [at] stool and eliminating the pulmonary conditi[on] causing the cough.

Reduced venous return to the heart m[ay] produce fainting in *pregnant women*, in who[m] the dorsal recumbent position, for prolong[ed] periods, causes obstruction of the inferior ve[na] cava through pressure exerted by the hea[vy] gravid uterus. The reduced venous return [to] the heart subsequent to the pooling of blo[od] which occurs in large *varicose veins* and veno[us] angiomas of the legs frequently results [in] lowering of the blood pressure.

Effort Syncope Due to Primary Pulmona[ry] Hypertension. Despite the normal oxygen sa[tu]ration of the blood which prevails in this d[is]ease and consequent absence of cerebral h[y]poxia, syncope occurs frequently. Strenuo[us] effort or emotional upset may cause an ac[ute] drop in blood pressure. This may be explain[ed] by the rise in the pulmonary arterial pressu[re] which causes stimulation of the nerve endi[ngs] in the pulmonary artery, with production o[f a] vagal reflex and a sudden fall in blood press[ure] with bradycardia.

Hypoxia. In *anemic states*, there is increa[sed] cardiac output to compensate for the redu[ced] oxygen-carrying capacity of the blood. [The] decreased peripheral resistance secondary [to] reflex arteriolar dilatation accompanying sev[ere] effort may result in syncope, in view of [the] existing hypoxia in the brain which acco[m]panies the anemia. Severe exertion in ot[her] hypoxic states, such as those which occur [at] *high altitudes* and *in congenital heart lesi[ons]* (tetralogy of Fallot, congenital atresia of [the] tricuspid valve), may result in sudden sev[ere] hypotension and syncope

Strenuous Exercise. In severe exercise th[ere] is a redistribution in the circulating bl[ood] volume. The total vascular bed is increa[sed] because of peripheral vasodilatation in [the] muscles, particularly of the legs. This redu[ces] the "effective circulating volume of the bloo[d,] producing hypotension, cerebral hypoxia, [and] syncope In the *superior caval syndrome*, sev[ere] effort or straining may result in sudden dist[en]tion of the cerebral veins, with resultant s[yn]cope Cerebral stagnation and hypoxia are [the] physiologi...

Chronic Valvular Disease of the Heart. In *aortic stenosis* associated with left ventricular hypertrophy, dizziness or syncope may result when sudden demands (strenuous effort) upon the cardiac output cannot be met because of the obstruction to blood flow by the stenotic valve, which prevents significant increase in the left ventricular stroke volume. Cerebral hypoxia may thus result, producing dizziness or faintness Similarly, in mitral, pulmonic, or tricuspid stenosis, severe dizziness or fainting may occur In these latter conditions, low blood pressures, occasionally approaching shock level, are found occasionally following exercise, presumably as a result of the failure of ventricular output to compensate for the increased demands resulting from the peripheral vasodilatation which occurs during strenuous exercise

Hypotension in Aviation. The sudden changes in atmospheric pressure to which an aviator may be subjected occasionally result in acute hypotensive episodes with syncope. *At extremely low atmospheric pressures,* the decreased atmospheric oxygen may result in dizziness and giddiness Furthermore, sudden *rapid acceleration* or *rapid deceleration* may cause "*black-outs*" at high altitudes Additionally, *air emboli,* with syncope and occasionally sudden death, may result from the release of nitrogen from the blood as a result of a sudden fall in the atmospheric pressure

Heat Exhaustion. Heat exhaustion is the result of acute peripheral vascular collapse In hot environments, there is an increased need for circulating blood in the skin, muscles, and brain

The environmental factors are temperature, humidity, and wind velocity There are increased circulatory demands of the skin to permit the dissipation of heat from the body via the blood vessels of the skin and via the sweat glands, which themselves require increased blood supply The sudden decrease in the peripheral vascular tone and the fall in cardiac output result in the failure of the body to maintain a peripheral blood supply adequate to satisfy the increased circulatory requirements The presence of a sodium deficiency may be predisposing

Nausea, vomiting, headaches, and syncope are the accompaniments The prognosis is good. Treatment consists of rest, increased salt intake, and attention to any cardiovascular disease that may be underlying

Heat Stroke. Heat stroke results from the failure of the sweat mechanism. There is a breakdown of temperature regulation because of the cessation of sweating, with elevation of body temperature up to 105°F. Mental confusion, staggering gait, headache, delirium, and coma characterize this syndrome. Secondary vasomotor shock and death occur if treatment is not immediately administered. The basic therapy consists of lowering the temperature to safe limits (if possible 102°F or below). This is done by immersing the patient in cool or iced baths or by spraying him with water, using a fan to produce rapid evaporation (Darling)

CHRONIC HYPOTENSION

In this category are included those patients who may suffer from repeated bouts of intermittent hypotensive crises (orthostatic hypotension) or protracted hypotensive states (Addison's disease, Simmonds's disease). Chronic hypotensive states, in contradistinction to the acute hypotensive states, do not require heroic treatment or immediate remedial procedures, as they are not critical or inimicable to the existence of the *individual.*

Primary "Idiopathic Orthostatic Hypotension." This condition was originally described by Bradbury and Eggleston (1925). The literature was reviewed in 1954 and the subject discussed; only about 50 cases had been reported until that time (Benestad et al). One new case was reported by those authors. The disease occurs most commonly in middle-aged males and is characterized by diastolic and systolic hypotension upon assuming the upright position, anhidrosis, and impotence (East et al). *The pulse rate, however, is not affected.* The term "idiopathic orthostatic hypotension" is adopted by Benestad, to distinguish from orthostatic hypotension, which is symptomatic of other disease states It was observed that in addition to the triad mentioned above, miosis and psychic disturbances were present. Electroencephalographic tracings demonstrated *cerebral ischemia in the* upright position. No changes were noted in electrocardiogram, and the heart rate remained unchanged The glomerular filtration rate and tubular reabsorption were diminished in the upright position Following syncope, there was an increase in a number of young leucocytes in the peripheral

blood. The urinary excretion of norepinephrine was decreased. This disease affected both the sympathetic and parasympathetic nervous systems. The usual sympathetic reflex, which causes vasoconstriction and compensates for the normal pooling of blood in the lower extremities upon standing, is absent. There is no apparent congestion of the lower extremities in these cases, while there is a definite decrease in venous return. Indicative of the disturbance in the parasympathetic nervous system is the fact that vagal stimuli (such as pressure upon the carotid sinus) fail to produce a response Although the etiology is unknown, it is most probable that idiopathic orthostatic hypotension is the result of some pathologic lesion in the hypothalamus affecting the autonomic nervous system It is postulated also that a hyposensitive carotid sinus or the failure of the adrenal glands to produce norepinephrine may be the physiologic mechanism in the production of this syndrome. The presence of leucocytosis may be an indication that cerebral hypoxia is providing the stimulus to the hypothalamus, which is thought to control the regulation of production of leucocytes.

Treatment thus far has been ineffectual in preventing idiopathic orthostatic hypotension The use of abdominal corsets and elastic bandages on the lower extremities has had poor success. Although no treatment based upon the etiology has been developed, symptomatic improvement by *"head-up" treatment*, in which the bed is raised during the night, and particularly by the use of *ephedrine* orally administered, has resulted in raised systolic and diastolic blood pressures The disease is progressive and the prognosis poor

Secondary (Chronic) Orthostatic Hypotension. Chronic orthostatic hypotension is characterized by fall in blood pressure upon assuming an upright position from the recumbent or squatting position. Weakness, dizziness, pallor, sweating, abdominal discomfort, and blurred vision may result. Occasionally, severely hypotensive episodes with syncope may ensue In most instances, except for idiopathic orthostatic hypotension discussed above, the condition is secondary to other disease states.

POSTSYMPATHECTOMY SYNDROME. In assuming the upright position following splanchnicectomy (generally performed in the treatment of essential hypertension), there is pooling of blood in the splanchnic area and in the lower extremities. The severence of the thoracolumbar sympathetic chain prevents the reflex arteriolar constriction which would otherwise occur. Consequently, there is a marked reduction in the circulating blood volume. Dizziness, dyspnea, and headache are characteristic symptoms. The condition generally lasts but a few months. The treatment consists of wearing an abdominal binder and elastic stockings.

CENTRAL NERVOUS SYSTEM DISORDERS In tabes dorsalis, syringomyelia, subacute combined degeneration, amyotrophic lateral sclerosis, encephalitis, and parkinsonism, there is an interruption of the sympathetic pathways depending upon the site of the pathologic lesion (hypothalamus, medulla, or spinal cord) and resulting in the loss of vasomotor tone, particularly arteriolar contraction. An additional factor is the pooling of blood in the splanchnic area and the lower extremities upon assuming the upright or sitting position, as a result of poor venous return secondary to the flaccid paralysis (loss of muscle tone) which accompanies these diseases. Treatment consists of the avoidance of overeating, sufficiently long periods of rest following meals, and the use of abdominal binders and elastic stockings.

CHRONIC DEBILITATING DISORDERS Protracted periods of bed rest occasioned by *extensive surgical procedures, severe acute infectious diseases* with prolonged convalescence, *chronic infectious diseases* (pulmonary tuberculosis), *rheumatoid arthritis, malnutrition*, etc, may result in orthostatic hypotension when these patients become ambulatory. Poor muscle tone results in the pooling of blood in the dependent portions so that there is reduced venous return to the heart In *primary atypical (viral) pneumonia*, there is thought to be loss of vasomotor tone owing to interference with the sympathetic vasomotor constrictor mechanism with reduced circulating blood volume resulting in postural hypotension Other chronic debilitating diseases frequently referred to in the literature as associated with hypotension are chronic alcoholism, parasitic infestations, lipoid nephrosis, poisonings, anorexia nervosa, ulcerative colitis, and carcinomatosis. Severe *opium poisoning* results in pronounced fall in the blood pressure, with tachycardia, pulmonary edema, and occasionally convulsive seiz-

ures. In less severe poisoning, nausea, vomiting, pruritus, drowsiness, sleep, and coma ensue.

Endocrinopathies. Chronic hypotension is found in Addison's disease, Simmonds's disease, hypothyroidism, and acromegaly.

In *Addison's disease,* symptoms of dyspnea and palpitation upon exertion do occur, but cardiac failure is uncommon The systolic blood pressures may vary from 80 to 100 mm Hg, and the diastolic may vary from 50 to 65 mm Hg Electrocardiographic changes are present but not typical. Low voltage, prolongation of the QRS interval, and inverted T-wave changes may be found. This may or may not reflect myocardial lesions and may represent the functional status of the adrenal cortex (electrolyte balance, circulating blood volume, etc) The heart size radiographically is smaller than normal, probably secondary to the loss of sodium and consequent loss of body fluids resulting in decreased circulating blood volume Severe shock (*Addisonian crises*) with severe hypotension, hemoconcentration, low sodium, high potassium, elevated blood urea nitrogen (renal failure due to low filtration pressure) may develop in a few hours when the individual is exposed to stressful situations such as childbirth, surgical procedures, severe upper respiratory infections, or gastrointestinal infections. These crises are thought to be due to failure of the individual to respond with increased adrenal cortical secretions and to further derangement of the electrolytic equilibrium owing to the loss of sodium and water.

The cardiovascular manifestations of *hypothyroidism* are due to the *myxedematous,* flabby myocardium, which results in reduced stroke volume and often, but not always, in lowering of the blood pressure The pulse rate remains unchanged The electrocardiogram may show T-wave inversions, low voltage, and prolongation of the QRS interval. Variability in a blood pressure cannot be explained, although cardiac output is reduced and circulation times are increased in most instances.

In far-advanced *acromegaly* and in *Simmonds's disease* (panhypopituitarism), hypotension exaggerated by postural changes is a frequent finding associated with syncopal attacks.

Chronic Cardiac Disorders. The following conditions may be associated with chronic hypotension: myocardial amyloidosis, fibroelastosis, constrictive pericarditis or pericardial effusion, and aortic stenosis. Occasionally, after severe myocardial infarction with shock, the hypotension may persist, even when shock has been successfully treated and overcome. This is apparently because of the persistence of reduced peripheral vascular resistance in view of a lack of reduction in cardiac output.

In *congestive heart failure,* the blood pressure is not lowered despite decreased cardiac output The probable explanation is a compensatory, peripheral vascular constriction.

blood. The urinary excretion of norepinephrine was decreased. This disease affected both the sympathetic and parasympathetic nervous systems. The usual sympathetic reflex, which causes vasoconstriction and compensates for the normal pooling of blood in the lower extremities upon standing, is absent. There is no apparent congestion of the lower extremities in these cases, while there is a definite decrease in venous return. Indicative of the disturbance in the parasympathetic nervous system is the fact that vagal stimuli (such as pressure upon the carotid sinus) fail to produce a response Although the etiology is unknown, it is most probable that idiopathic orthostatic hypotension is the result of some pathologic lesion in the hypothalamus affecting the autonomic nervous system. It is postulated also that a hyposensitive carotid sinus or the failure of the adrenal glands to produce norepinephrine may be the physiologic mechanism in the production of this syndrome The presence of leucocytosis may be an indication that cerebral hypoxia is providing the stimulus to the hypothalamus, which is thought to control the regulation of production of leucocytes.

Treatment thus far has been ineffectual in preventing idiopathic orthostatic hypotension The use of abdominal corsets and elastic bandages on the lower extremities has had poor success. Although no treatment based upon the etiology has been developed, symptomatic improvement by *"head-up" treatment*, in which the bed is raised during the night, and particularly by the use of *ephedrine* orally administered, has resulted in raised systolic and diastolic blood pressures The disease is progressive and the prognosis poor

Secondary (Chronic) Orthostatic Hypotension. Chronic orthostatic hypotension is characterized by fall in blood pressure upon assuming an upright position from the recumbent or squatting position. Weakness, dizziness, pallor, sweating, abdominal discomfort, and blurred vision may result Occasionally, severely hypotensive episodes with syncope may ensue In most instances, except for idiopathic orthostatic hypotension discussed above, the condition is secondary to other disease states

POSTSYMPATHECTOMY SYNDROME In assuming the upright position following splanchnicectomy (generally performed in the treatment of essential hypertension), there is pooling of blood in the splanchnic area and in the lower extremities. The severence of the thoracolumbar sympathetic chain prevents the reflex arteriolar constriction which would otherwise occur. Consequently, there is a marked reduction in the circulating blood volume. Dizziness, dyspnea, and headache are characteristic symptoms. The condition generally lasts but a few months. The treatment consists of wearing an abdominal binder and elastic stockings

CENTRAL NERVOUS SYSTEM DISORDERS In tabes dorsalis, syringomyelia, subacute combined degeneration, amyotrophic lateral sclerosis, encephalitis, and parkinsonism, there is an interruption of the sympathetic pathways depending upon the site of the pathologic lesion (hypothalamus, medulla, or spinal cord) and resulting in the loss of vasomotor tone, particularly arteriolar contraction. An additional factor is the pooling of blood in the splanchnic area and the lower extremities upon assuming the upright or sitting position, as a result of poor venous return secondary to the flaccid paralysis (loss of muscle tone) which accompanies these diseases. Treatment consists of the avoidance of overeating, sufficiently long periods of rest following meals, and the use of abdominal binders and elastic stockings.

CHRONIC DEBILITATING DISORDERS Protracted periods of bed rest occasioned by *extensive surgical procedures, severe acute infectious diseases* with prolonged convalescence, *chronic infectious diseases* (pulmonary tuberculosis), *rheumatoid arthritis, malnutrition*, etc., may result in orthostatic hypotension when these patients become ambulatory. Poor muscle tone results in the pooling of blood in the dependent portions so that there is reduced venous return to the heart In *primary atypical (viral) pneumonia*, there is thought to be loss of vasomotor tone owing to interference with the sympathetic vasomotor constrictor mechanism with reduced circulating blood volume resulting in postural hypotension. Other chronic debilitating diseases frequently referred to in the literature as associated with hypotension are chronic alcoholism, parasitic infestations, lipoid nephrosis, poisonings, anorexia nervosa, ulcerative colitis, and carcinomatosis Severe *opium poisoning* results in pronounced fall in the blood pressure, with tachycardia, pulmonary edema, and occasionally convulsive seiz-

ABNORMAL CAROTID SINUS REFLEX

A variety of causes and predisposing factors are responsible for *increased sensitivity* of the carotid sinus. *Local causes* include inflammation or enlarged lymph nodes, tumor masses, adhesions, or scar tissue in the neck. Aneurysmal dilatation or arteriosclerotic alterations within the sinus itself belong to this category. Syphilis, brain tumors, and skull fractures may be responsible for hypersensitivity of the central connections in the medulla. Irritability of the efferent arc of the reflex may arise from arteriosclerosis, hypertension, and coronary artery disease. *Digitalis* is an important sensitizing agent of the peripheral vagal endings in the heart. Age and sex are contributing factors. The carotid sinus syndrome is common in the male, particularly the aged. The menopause also predisposes to sensitivity of the carotid sinus reflex. Neurotically conditioned individuals are particularly vulnerable. Other predisposing or contributing causes include nutritional deficiency, particularly of thiamine; biliary tract and esophageal disease, contralateral carotid artery thrombosis, and hypoxemic or hypoglycemic states. The erect posture and certain neck movements are important precipitating factors. In susceptible individuals, the carotid sinus syndrome may be set in motion by turning the head suddenly to one side during the process of shaving, or by stooping, coughing, or straining. Chiropractic manipulation and trauma to the neck may be responsible for attacks. Any surgical or anesthetic procedure in which the patient is maintained in an upright posture, and the neck is hyperextended or manipulated, sensitizes the reflex.

Depending on the efferent pathway involved, three types of carotid sinus syncope have been described (Weiss, S.). The first, or *vagal type*, is characterized by marked slowing of the heart, varying from sinus bradycardia to complete asystole depending on the degree of vagal activity. From its inhibitory effect on the AV conduction system, all types of AV block may develop. Occasionally, atrial flutter or fibrillation has been observed. The cerebral symptoms observed in this type result primarily from slowing of the heart and the consequent fall in blood pressure. A hypersensitive carotid sinus reflex may form the basis for a Stokes-Adams syndrome.

The second, or *depressor type* of carotid sinus syncope, is uncommon and is characterized by a sudden drop in arterial pressure without significant slowing of the heart. Cerebral symptoms are secondary to peripheral vasodilatation.

The third, or purely *cerebral type* occurs without either slowing of the heart or fall in blood pressure. The mechanism of this type is the least understood. It has been suggested that certain areas of the brain are stimulated. A more logical explanation is that actual impairment of the carotid flow to the brain is the underlying cause.

Clinically, the carotid sinus syndrome is usually a combination of two or more types. A fourth, or *mixed, type* should therefore be included in the classification. A common type *is a combination of the vagal and depressor syndrome.*

The *symptoms* observed in the carotid sinus syndrome follow no fixed pattern. The onset may be ushered in with prodromal symptoms consisting of visual blurring, scotomas, unsteadiness, dizziness, weakness, lightheadedness, nausea, epigastric distress, and tinnitus. Paresthesias of the face or extremities occur on the side contralateral to the affected sinus because of the commonly encountered decussation of nervous pathways. Syncope follows and is of short duration. The muscles are flaccid, and there is a facial pallor followed by a flush and diaphoresis. Breathing is slow and shallow. Convulsions, in some cases unilateral, are usually associated with syncope. In the cerebral type, however, convulsions may appear independently of loss of consciousness. It should be emphasized that in many individuals with the carotid sinus syndrome, mild symptoms, without syncope or convulsions, are common.

The diagnosis of carotid sinus syndrome is frequently missed. It should be suspected in any patient who presents a history of unexplained dizziness, weakness, syncope, convulsions, or related manifestations. In the *differential diagnosis*, the following conditions should be considered: epilepsy, cataplexy, hypoglycemia, Ménière's disease and vertigo, hyperventilation syndrome, hysteria, heart block, cardiac arrhythmias and paroxysmal tachycardias, postural hypotension, and vasovagal disorders.

Reproduction of the exact symptoms by

The carotid sinus syndrome

JACOB J. SILVERMAN AND SIEGFRIED SALOMON

Approximately a century and a half ago Parry first observed that pressure on the neck along the course of the carotid artery gave rise to a slowing of the heart. The relationship between the carotid artery and syncope, however, had been known since ancient times. It is now known that certain mammals, notably horses and goats, depend entirely on the carotids for their cerebral blood supply, as the vertebral arteries are poorly developed.

THE CAROTID SINUS

The carotid sinus is a short, thin-walled, slightly bulbous dilatation of the common carotid artery, located bilaterally near its bifurcation into the internal and external carotid arteries. Occasionally the sinus dilatation involves a portion of the internal carotid artery as well The walls of the sinus contain an extensive nervous network of highly specialized myelinated sensory end organs (*pressoreceptors*), which are most numerous between the connective tissue fibers within the tunica adventitia. This unique anatomic arrangement permits easy stimulation when the arterial wall is stretched Similar receptors are found in the arch of the aorta, in the bronchioles, and in various blood vessels throughout the body. The afferent arc of the carotid sinus reflex originates in the specialized receptor cells of the sinus wall to form the *carotid sinus nerve* ("sinus nerve of Hering," "intercarotid nerve of de Castro"), which in turn ascends between the internal and external carotid arteries to join the glossopharyngeal nerve. Fibers of the afferent arc terminate centrally in the cardioregulatory, vasomotor, and other autonomic centers in the medulla. The final efferent pathways are by way of the vagal and cervical sympathetic connections (Part 1, Chap. 14).

THE CAROTID SINUS REFLEX

The carotid sinus reflex is an important physiologic mechanism for the maintenance of a uniform blood pressure and an adequate blood supply to the brain. It is particularly important in states of stress. A sudden rise in arterial pressure stretches the wall of the carotid sinus Since the receptor end organs of the carotid sinus are stimulated by stretching of the sinus wall, a sudden rise in intraarterial pressure initiates a series of cardiovascular reflexes and thereby causes a prompt lowering of the blood pressure and a slowing of the heart Conversely, a decline in intrasinal pressure reflexly initiates vasoconstriction and tachycardia. The normal function of the carotid sinus reflex is reflected chiefly in its tonic effect on the cardiovascular system Indirectly, however, it is capable of widespread reactions through its connections with a number of autonomic centers in the medulla. Hence, activity of the carotid sinus may influence respiration, skeletal muscle and bladder tone, gastrointestinal activity, and the secretion of epinephrine. Because of its close anatomic relationship, the carotid body is sometimes confused with the carotid sinus. The carotid body, however, is a *chemoreceptor* organ and is stimulated by hypoxia, increased carbon dioxide tension, and a number of drugs Its principal action is related to respiration, but through sympathetic activity, it also influences the blood pressure and pulse rate (Part 2, Chap 12).

Vasovagal syncope

JACOB J. SILVERMAN AND SIEGFRIED SALOMON

A common form of syncope is vasovagal syncope, or *simple fainting* It occurs more frequently than all other types of syncope combined Attacks always occur in the standing or sitting position and are relieved by recumbency Fainting as a result of *prolonged standing* is a familiar example of vasovagal syncope An ordinary venipuncture may provoke an attack in a robust individual. Most attacks are benign In the aged or in the presence of organic heart disease, however, this syndrome can be fatal In the enthusiasm to encourage ambulation, hospital patients are sometimes forcibly propped up in a wheel chair or armchair Such patients, particularly if debilitated, may easily develop vasovagal syncope If recumbency is not quickly established in these patients, death may promptly follow Similarly, the upright posture in certain operative procedures may be responsible for a number of unexplained anesthesia deaths

The syndrome of vasovagal syncope is a reflex disturbance conditioned by many factors Fear, anxiety, and pain, either imaginary or real, are common predisposing causes The following are some of the more important cardiovascular situations in which the vasovagal syndrome may be observed.

1 Prolonged recumbency and convalescent states, especially in elderly persons

2 Peripheral circulatory failure

3 Any tachycardia with a ventricular rate of over 160 per minute

4 Embolic or infarction states

5 Aortic valvular disease

6 Sudden visceral catastrophes (acute pancreatitis)

7 Ordinary venesection or paracentesis

8. Loss of blood, internal or external

9 Electrolytic disturbances and dehydration

10 Hypoglycemic states

11. Hypertensive encephalopathy

12 Localized cerebrovascular disease

13 Reflex hyperventilation state

14. Side reaction to drugs (ganglionic blocking agents)

The mechanism of vasovagal syncope is complicated and not entirely understood. It occurs under such a wide variety of circumstances that it is probable that multiple reflexes or mechanisms are involved. It is interesting that between attacks, patients with this syndrome almost invariably demonstrate no abnormalities. The important role of emotional influences has been discussed in detail by Engel (1950). In biologic terms, loss of consciousness as a reaction to fear or danger may represent a primitive protective response to conserve the total organism "Sham death" is a lifesaving device in certain animals when exposed to overwhelming danger.

During an attack of vasovagal syncope, many features of shock are present The basic disturbance may well represent a hypersensitivity of the splanchnic vascular system. As a result of this disturbance, blood accumulates in the dilated splanchnic vessels, cardiac output drops, and there is a peripheral circulatory collapse The elevation in diastolic pressure and rise in pulse rate observed just before the faint are obviously due to a compensatory mechanism. When this mechanism fails, the blood pressure abruptly falls and syncope develops. The slow heart rate observed during the stage of syncope is a result of increased

applying pressure over the carotid sinus is the only sure way of confirming the diagnosis. It should be emphasized that artificial stimulation of the carotid sinus in clinically normal individuals is capable of producing a wide variety of symptoms and electrocardiographic changes, including asystole. To repeat, if the symptoms produced by artificial stimulation of the carotid sinus are not an exact reproduction of those experienced during attacks, the diagnosis of a hypersensitive carotid sinus syndrome should be doubted or discarded.

Artificial testing for carotid sinus sensitivity may be hazardous and requires careful attention to certain details. The patient should be seated on the edge of the examining table with the head slightly extended. An attempt should be made to identify the bulb of the carotid sinus. Although not always easily located, the landmark is the angle between the larynx and the anterior margin of the sternocleidomastoid muscle at the level of the thyroid cartilage. After the sinus is located, it is manually compressed against the cervical spine and mildly massaged for not more than 30 sec, unless the diagnosis is established earlier. If an insignificant response is obtained, multiple areas are stimulated in order to eliminate anatomic variations of the location of the carotid sinus. The right side of the neck is first stimulated, since this side is usually the more sensitive. However, if no response is obtained on the right side, the procedure is repeated on the left. Under no circumstances should *both* carotid sinuses be tested simultaneously. With the aid of an assistant, the blood pressure and pulse rate are recorded. A continuous electrocardiographic tracing is valuable. If an attack is induced, it is often desirable to repeat the test after the patient has been atropinized. In doubtful cases, it may be necessary to repeat the test after novocainization of the sinus.

Testing for carotid sinus sensitivity is not without risk, particularly in the aged. Serious neurologic complications have been reported following carotid sinus stimulation. Recovery from spontaneous and induced syncopal attacks, however, is usually prompt and uneventful.

Therapy. Therapy of the carotid sinus syndrome will depend largely upon the frequency and nature of attacks, as well as on the predisposing causes. Immediate treatment usually consists in placing the patient in a comfortable horizontal position with the head lowered. All tight clothing should be loosened and any pressure around the neck relieved. Vigorous antishock treatment is rarely necessary, but epinephrine is the drug of choice if there are signs of vasomotor collapse or if the heart rate is extremely slow.

Any localized or potential source of pressure in the region of the carotid sinus should be investigated. Avoidance of a tight or high collar may be curative. Inflamed lymph glands or tumors adjacent to the carotid sinus should be appropriately treated.

Unilateral surgical section of the nerve or *denervation of the carotid sinus* is occasionally necessary if attacks occur at frequent intervals and are disabling. As a last resort, if sinus denervation fails, section of the intracranial portion of the glossopharyngeal nerve should be considered. In recent years, a promising number of patients with the carotid sinus syndrome have been treated successfully by x-ray irradiation of the sinus.

For the prevention of the vagal or cardioinhibitory reflexes, cholinergic blocking drugs are prescribed. These include atropine, belladonna, scopolamine, and *Banthine.* Sympathomimetic drugs are also valuable, since they increase the excitability of the myocardium, counteract ventricular slowing, and thus prevent cardiac arrest; epinephrine, ephedrine, *Isuprel, Paredrine, Benzedrine,* and *Neo-synephrine* belong to this category. In the group of cases with the predominant vasodilator reflex (the vasodepressor type), the sympathomimetic drugs, particularly epinephrine, are indicated. In the absence of cardiac slowing, the cholinergic blocking drugs are not used. Drug therapy in the cerebral type of reflex is of little or no value.

Wherever possible, attempts should be made to improve the patient's general physical and mental health. Any metabolic disturbance or nutritional deficiency, particularly thiamine deficiency, should be corrected. Tobacco, coffee, digitalis, insulin, and morphine may be predisposing sensitizing agents. Any related reflex disturbance, such as biliary tract disease, should be corrected or eliminated, if possible. For many patients, a cure is not obtainable, and continuous prophylactic administration of atropine, alone or in combination with a sympathomimetic drug, may be necessary.

3

Vasovagal syncope

JACOB J. SILVERMAN AND SIEGFRIED SALOMON

A common form of syncope is vasovagal syncope, or *simple fainting* It occurs more frequently than all other types of syncope combined Attacks always occur in the standing or sitting position and are relieved by recumbency. Fainting as a result of *prolonged standing* is a familiar example of vasovagal syncope. An ordinary venipuncture may provoke an attack in a robust individual. Most attacks are benign In the aged or in the presence of organic heart disease, however, this syndrome can be fatal In the enthusiasm to encourage ambulation, hospital patients are sometimes forcibly propped up in a wheel chair or armchair Such patients, particularly if debilitated, may easily develop vasovagal syncope If recumbency is not quickly established in these patients, death may promptly follow Similarly, the upright posture in certain operative procedures may be responsible for a number of unexplained anesthesia deaths

The syndrome of vasovagal syncope is a reflex disturbance conditioned by many factors Fear, anxiety, and pain, either imaginary or real, are common predisposing causes. The following are some of the more important cardiovascular situations in which the vasovagal syndrome may be observed

1 Prolonged recumbency and convalescent states, especially in elderly persons
2 Peripheral circulatory failure
3 Any tachycardia with a ventricular rate of over 180 per minute
4 Embolic or infarction states
5. Aortic valvular disease
6 Sudden visceral catastrophes (acute pancreatitis)
7. Ordinary venesection or paracentesis
8. Loss of blood, internal or external
9 Electrolytic disturbances and dehydration
10 Hypoglycemic states
11. Hypertensive encephalopathy
12. Localized cerebrovascular disease
13 Reflex hyperventilation state
14 Side reaction to drugs (ganglionic blocking agents)

The mechanism of vasovagal syncope is complicated and not entirely understood. It occurs under such a wide variety of circumstances that it is probable that multiple reflexes or mechanisms are involved. It is interesting that between attacks, patients with this syndrome almost invariably demonstrate no abnormalities The important role of emotional influences has been discussed in detail by Engel (1950). In biologic terms, loss of consciousness as a reaction to fear or danger may represent a primitive protective response to conserve the total organism "Sham death" is a lifesaving device in certain animals when exposed to overwhelming danger

During an attack of vasovagal syncope, many features of shock are present The basic disturbance may well represent a hypersensitivity of the splanchnic vascular system. As a result of this disturbance, blood accumulates in the dilated splanchnic vessels, cardiac output drops, and there is a peripheral circulatory collapse The elevation in diastolic pressure and rise in pulse rate observed just before the faint are obviously due to a compensatory mechanism When this mechanism fails, the blood pressure abruptly falls and syncope develops. The slow heart rate observed during the stage of syncope is a result of increased

vagus tone and is a secondary effect. That the cardiac slowing is not causative but secondary can be demonstrated by the experimental administration of atropine. This drug, in doses of 1 or 2 mg, will abolish the slow heart rate and heart block but fails to prevent loss of consciousness.

The *symptoms* of vasovagal syncope are brief and dramatic. The onset takes place within a matter of seconds to a few minutes. The earliest symptom is a feeling of *apprehension*, followed by *muscular weakness*, *epigastric distress* with *nausea* or *retching*, *sweating*, *sighing type of respiration* or yawning, *tremors*, and finally *collapse*. Precordial pain and a sense of rotation are conspicuously absent. There are many gradations of vasovagal syncope; in the *mild type*, symptoms are variable and minimal. An important feature of the syndrome is the relief obtained by the recumbent posture Recovery is usually prompt During a *severe attack*, when the patient is deeply unconscious, a flurry of excitement surrounds the event. The patient in fact may appear to be dying. The face is frightfully pale and drenched with sweat. The hands are cold and moist; the radial pulse is imperceptible. Respirations follow no set pattern; they may be slow, deep, or shallow. The pupils are dilated and the reflexes may be lost. The muscles are flaccid and limp, occasional clonic muscular movements are seen

Following the attack, which is usually over within a few minutes, patients complain of muscular weakness and poor coordination, and are often left with a severe headache lasting for several hours. As a result of the fall they may have suffered from a serious laceration, a dislocation, or a fracture.

The immediate *management* of vasovagal syncope ordinarily is simple The patient is placed in a horizontal position with *the head lowered*. Spontaneous recovery is the rule All tight clothing is loosened. After consciousness has returned, it is wise to have the patient continue to lie flat until normal muscular power has returned. If he is permitted to sit up too quickly, symptoms are apt to recur Exercising the legs in a recumbent position is desirable. In prolonged attacks, parenteral administration of atropine and epinephrine occasionally may be indicated. The patient should always be examined for blood loss or serious injury. Rarely, if cardiac arrest supervenes, artificial respiration and cardiac massage should be attempted, or if a cardiac pacemaker is available, external electric stimulation is administered.

Vasovagal syncope tends to be repetitive, an attempt therefore should always be made to treat or remove the predisposing cause Any metabolic, nutritional, or electrolytic disturbance should be corrected. An abdominal support or a corset may be valuable in patients with flabby musculature. Prolonged standing or maintenance of an erect posture in susceptible individuals should be avoided Obviously, if there are profound emotional disturbances, the patient may require intensive psychiatric treatment.

Shock

Shock in General

EDWARD D. FRANK

Metabolic Aspects of Shock

STANLEY LEVENSON AND ALBERT EINHEBER

SHOCK IN GENERAL

Shock is a circulatory disorder in which the basic defect is *an acute persisting deficiency of peripheral blood flow*. Progressive and widespread deterioration of function is the inevitable result. The rate and extent of the deterioration depend upon the severity and duration of the deficiency in flow. Since lethal tissue damage due to shock may occur insidiously within minutes or hours, immediate recognition of the state of shock is essential, so that aggressive and effective treatment may be instituted.

PATHOPHYSIOLOGY

By definition, shock implies trauma. But the trauma need not be overt physical destruction of tissue. It may also be *chemical, as from a drug or a bacterial toxin*. Except for infection, the initial blow is a *circulating blood volume deficit*, as by hemorrhage, burns, or dehydration, or by regional segregation of blood, e.g., in acute occlusion of portal blood flow, or an acute or *primary insufficiency of cardiac output*, in which there is inadequate blood flow in the tissues. The body compensates immediately by *widespread vasoconstriction*, which varies in intensity in different areas, by the shift of fluid from the extravascular compartments, and by increasing the heart and respiratory rates. In infection, the two above defects may exist (e.g., peritonitis or myocarditis) or the primary disturbance may be *damage of the small blood vessels*.

As shock of any cause continues, the peripheral vascular phenomena which have been observed both clinically and experimentally include vasoconstriction, loss of *vasomotion*, and a swamplike flow in the capillaries and venules. As *venous return declines* progressively, cardiac output follows suit. The effect of deficiency of flow in any given area depends in part upon local compensatory mechanisms. Thus, the brain retains a greater fraction of the available blood flow than the skin and subcutaneous tissues.

The persistence of deficient peripheral flow and the cumulative tissue hypoxia lead to a progressively catabolic state. Metabolic *acidosis* develops. Blood pH and P_{CO_2} decrease, plasma lactate and pyruvate increase, tissue high-energy phosphate is depleted (Rosenbaum et al.). Secretory function declines or disappears. Evidence of *hepatic dysfunction* includes glycogen depletion and late decline in blood sugar, inability to synthesize fibrinogen, prothrombin, and other proteins (Frank, E. D., et al., 1953); increased plasma amino acids (Seligman et al., 1948), evidence of decreased hepatic blood flow (decreased bile secretion, decreased Bromsulfalein clearance). Evidence of *renal insufficiency* includes any or all of the findings of *uremia* (serum potassium elevation may be aggravated by tissue damage). The brain, heart, and adrenal glands still function fairly well unless shock is severe or prolonged.

If recognition of the shock state is too late,

or treatment inadequate, post-mortem examination commonly reveals very little to account for the failure to recover. The causative factor may be evident, but the mechanism of death is frequently obscure. Scattered small hemorrhages in the wall of the intestine are common

EXPERIMENTAL STUDIES

A summary of all the significant work on shock will not be made. The authors propose merely to present an account of the efforts of their laboratory over a period of years (1940–1958) to arrive at a valid concept of the nature of the irreversibility phenomenon Most of the discussion to follow is based upon data derived from a standardized method of producing hemorrhagic shock with predictable consequences. The technique embraces two main principles: (1) that the arterial pressure be maintained at a constant low level, and (2) that the duration of hemorrhagic hypovolemia be determined by physiologic response rather than by arbitrary time limits

Healthy mongrel dogs weighing 18 to 20 kg, fasted 12 hr, given morphine premedication (1 to 2 mg/kg, intramuscularly), and not given barbiturate or general anesthesia, are cannulated under local anesthesia The animal is bled from a femoral artery into an open reservoir elevated at such a height that an arterial pressure of 30 to 40 mm Hg is obtained. Blood clotting in the external system is prevented by the use of small amounts of heparin. Within 30 to 60 min, the blood level in the reservoir reaches a maximum After a variable interval, blood returns to the animal, indicating the failure of compensatory mechanisms. If the blood in the reservoir is reinfused within 2 hr, permanent survival is usually effected (90 per cent) If, on the other hand, the hypotension is allowed to continue, by the fourth hour somewhat less than half the maximum bleeding volume will have returned from the reservoir spontaneously If, at this point, the remainder of the blood in the reservoir is infused intravenously, the arterial pressure will rise toward the initial level and then exhibit a secondary decline. Over 90 per cent of such animals die within 12 hr Post-mortem examination shows no abnormality other than scattered small intestinal hemorrhages and a variable degree of hepatic, renal, splenic, and pulmonary congestion If large volumes of blood or blood substitutes are used in an effort to sustain the circulation, the congestion will be more marked

The condition of these animals is irreversible by blood replacement. They also succumb when treated with additional transfusions (blood substitutes as well as electrolyte solutions), pressor drugs including nor epinephrine, adrenal steroids and ACTH, adrenolytic drugs (except when given prophylactically—see below), and correction of electrolyte disturbances by artificial dialysis Eventually, it seemed likely that the condition under investigation might be a refractory hemodynamic state related to the *functional failure of a critical organ or tissue,* and that after normovolemia had been restored, efforts to stimulate the circulation were beside the point. The brain, heart, lungs, and adrenal glands seemed to be functioning too well to play this role. Renal failure seemed unlikely because of the speed of death. Because of the numerous vital functions of the liver and its special dependence on portal venous blood, which is notoriously low in oxygen content in shock, *the liver* of the animal in shock was perfused by arterial blood, via the portal vein, from a normal donor in balanced cross circulation (Seligman et al., 1947b). *This resulted in a substantial percentage of survivors,* whereas cross circulation via a systemic vein instead of the portal vein was of no value. Was the liver at fault for the loss of a critical function, or because it was the source of a poison generated during sustained anoxia? Most of the dog's tissues in the normal state contain clostridia If they were responsible, *penicillin* should help. When penicillin was administered before the institution of hemorrhage, there was a high percentage of survivors. But pretreatment with polyvalent clostridial antitoxin failed to help. A wide variety of antibiotics was then administered by various routes and at different times before and during shock (Frank, H. et al, 1952c). Pretreatment was found to be necessary to produce survival Even when the antibiotics were administered beginning with the institution of hemorrhage, they were likely to be ineffective. Perhaps most interesting of all was the fact that pretreatment consisting of administration of nonabsorbable antibiotics (*neomycin*) by mouth resulted in survival rates as high as those obtained by any other method, if not higher Although parenteral administration of anti-

biotics was almost as effective as the oral route, the fact that oral neomycin was very effective suggested the importance of the intestinal flora. Moreover, since neomycin does not act against clostridia, these bacteria seemed unimportant

Infection, as it is recognized clinically, was nowhere evident. Blood cultures taken during all phases of shock were uniformly sterile.[1] But many blood and tissue cultures taken just a few minutes after death were positive for a variety of enteric organisms. Thus, the permeability of the intestinal barrier to bacteria or their products came into question as a possible key factor. Nelson reported that botulinus toxin is absorbed from the gut more rapidly in shock than in the normal state. But this is a diffusible toxin and may not reflect the behavior of other types of toxins, e g, endotoxins There is good reason, nevertheless, to assume that bacteria, and perhaps their products, are continuously invading the blood stream during the normal state. This can explain the clostridia in the dog's tissues and other enteric bacteria in tourniqueted muscle. Direct evidence that the gut is permeable to bacteria was obtained by the induction of tourniquet shock in the rat (Friedman et al). This species was chosen because its tissues are uniformly sterile in the normal state. When the muscle of the tourniqueted limb is cultured before release of the tourniquet, it is uniformly sterile, but after removal of the tourniquet, it may exhibit bacteria of intestinal origin If infection from enteric bacteria is responsible, why were they not being cultured during life from the blood and tissues?

Was it possible that the organism in shock is supersensitive to bacteria or their toxins? If so, the few necessary bacteria or their products might be hard to demonstrate. The absence of the signs of infection had already been explained on the basis of the inability of the organism in shock to respond in the usual manner to a bacterial challenge. On the basis of this speculation, experiments were initiated which yielded evidence that there is indeed a markedly lowered resistance to bacteria and their products in shock. This evidence included the demonstration that the phagocytic and bacteriostatic capacity of polymorphonuclear leucocytes and macrophages in shock plasma is reduced[2] (Schweinburg et al, 1955, Rutenburg et al.), that the microscopic appearance of polymorphonuclear leucocytes in shock plasma is abnormal (they simulate "lupus erythematosus cells" with loss of distinct cell membranes, eccentric nuclei, and atypical granules) (Rutenburg *et al.*), *that* the resistance to intravenously injected bacteria of a dog subjected to reversible *hemorrhagic* shock is markedly reduced[3] (Schweinburg et al., 1955), that the *titer of properdin* declines early and severely in hemorrhagic shock[4] (Frank et al, 1955), and that the vulnerability to *endotoxin is* enormously increased (Schweinburg et al., 1954).[5] This last observation *provided quantitative* evidence of a remarkable degree of lowering of resistance to bacterial *products*, even in transient, i e., reversible shock, and confirmed the suspicion that *the amount* of bacterial activity required to produce a lethal effect in shock might be

[1] Time was taken to explore the possibility that

gently to destroy antibacterial potency without altering chemical integrity. Another approach was the study of the effect of antibiotics on the high-energy phosphate content of the liver in shock (Rosenbaum et al.). ...
ing in
nificant

[2] This has been confirmed by the finding that the expected enhancement of the respiratory activity of leucocytes during phagocytosis does not occur in *the presence* of shock plasma (Karnovsky).

[3] These animals succumb to a dose of intra-

[4] This component of *normal serum*, discovered by Pillemer, has been shown to have potent antibacterial activity, especially against gram-negative organisms but *also* against certain gram-positive organisms and viruses

[5] This *experiment* was done in the rabbit because it is possible to assay purified toxins fairly accurately in this species. The toxin used was an *Escherichia coli* endotoxin. The lethal *dose (MLD/100)* of *this toxin* for normal rabbits weighing 5 lb was 0 13 mg The lethal dose (MLD/100) for rabbits previously subjected to less than 2 hr of hemorrhagic hypotension, which alone is uniformly well tolerated, was only 0 00001 mg

so small as to be difficult to detect. On the basis of this finding, it was possible that no more invasion of bacteria or their products than occurs in the normal animal is sufficient to produce fatal peripheral vascular collapse in this very sensitive state.

But all this evidence merely inferred a possible bacterial factor in shock. Confirmation of the presence of a circulating toxin in shock became an essential condition for the validation of the thesis that irreversibility to transfusion is due to a bacterial factor. This was secured during the past year. A search for a poison had been made by many investigators (Moon; Green; Aub, Shorr et al.). The transfer of shock blood to normal recipients does not induce any obvious disturbances. In 1954, however, it had been demonstrated that normal recipients (dogs) tolerated the intraperitoneal injection of homogenated liver from normal or shocked animals, whereas recipients exposed to hemorrhagic shock from which recovery could be expected (transfusion after 2 hr), died if injected with shock liver but recovered if injected with normal liver (Schweinburg et al, 1957). Thus, shock liver contains a substance which is lethal to an animal with lowered resistance. That this was a bacterial substance was demonstrated by prevention of death of the shock recipient by giving him penicillin. A similar technique was applied to test the blood instead of the liver. In both dogs and rabbits, subjected to 2 hr or less of hemorrhagic shock and then transfused with blood from a donor animal in late shock (irreversible), the course in the otherwise reversible recipient is uniformly fatal (Schweinburg et al). These recipients show the characteristic clinical physiologic responses of animals in irreversible hemorrhagic shock and, after death, demonstrate the usual intestinal hemorrhages. Efforts to identify the noxious factor in shock blood have thus far demonstrated that *it resides in the plasma fraction of the blood and that it is a polysaccharide* when extracted according to the Boivin technique (Ravin et al.) It is thus consistent with, but not yet identified as, an endotoxin. Further studies have shown that shock plasma produces the same biologic reactions as intravenously administered endotoxin. Thus in rabbits, there is the characteristic early and remarkable disappearance of circulating polymorphonuclear leucocytes, the typical fever response, the presumably specific generalized Shwartzman reaction (Ravin et al.), and also the induction of tolerance by the "immunizing" administration of either endotoxin or shock plasma (not by normal plasma) against prolonged hemorrhagic hypotension (such animals survive 6 hr of hemorrhagic shock, which is uniformly fatal to unimmunized rabbits) (Smiddy et al.).

Efforts are being made to identify further this lethal factor and to determine the mechanism of its action. Is it a polysaccharide derived not from bacteria but from hypoxic tissues? Landy and Shear have shown that such "tissue toxins" are capable of producing biologic reactions very similar to those of bacterial endotoxins. If endogenous tissue toxins are the lethal factor, it is impossible to answer the question as to how the antibiotics, especially the nonabsorbable intestinal antibiotics, protect against the elaboration of lethal amounts of such tissue toxins during the prolonged anoxia induced by hemorrhagic hypotension. As for the mechanism of action of bacterial endotoxins, there is now much interesting information, which can be summarized briefly by the statement that Reilly, Delaunay, and later Thomas have provided evidence that *these toxins may act via adrenergic pathways* The injection of epinephrine into dogs and rabbits causes disappearance of circulating polymorphonuclear leucocytes, produces fine blood vessel changes similar to those produced by endotoxin, and when injected into the skin following a dose of intravenous endotoxin, produces a markedly enhanced localized necrotizing reaction (Thomas; Zweifach et al, 1956). Furthermore, it has been shown that antiadrenergic drugs, such as *dibenamine*, may be protective in certain forms of shock (Nickerson et al.) and may prevent the lethal outcome when shock blood is transferred to recipients with lowered resistance but protected with dibenamine (Smiddy) But these matters must await future study and experimentation.

The author's present concept of the pathogenesis of shock may be summarized as follows: In shock of any type, generalized tissue anoxia results in marked lowering of resistance to bacteria and their products These products, coming from sites of infection or from the gut

lumen, exert a damaging influence upon the fine blood vessels, possibly via adrenergic pathways, thus aggravating the peripheral vascular insufficiency. The established vicious cycle hastens death (Fig. 14-1).

CLINICAL MANIFESTATIONS

The characteristic features of shock are:

1 *Cold, pale, moist skin*—evidence of the response of the sympathetic nervous system to blood volume deficit or tissue hypoxia There is *widespread vasoconstriction*. Because of the reduced rate of flow in the peripheral vessels, there is *cyanosis* as well as *pallor*, most readily observed in the nail beds and mucous membranes.

2 *Oliguria or anuria*—evidence of reduced renal blood flow

3 *Mental and physical apathy*. Early in shock the patient may be apprehensive and exhibit anxiety owing to release of epinephrine

4. *Hypotension* and *tachycardia*. In many instances, the hypotension is caused directly by reduced blood volume In others, in which there is no deficit (e g , sepsis without significant fluid loss), the *reduced cardiac output* is due to *deficient venous return* owing to stagnation in the periphery because of collapse of the peripheral vascular system.

Infection, a frequent etiologic agent, may be concealed or difficult to detect because of the inability of the organism to respond Therefore, there may be *no* fever, pain, or leucocytosis

LABORATORY DATA

Shock is diagnosed on the basis of bedside evidence Laboratory data are generally not useful for diagnosis but may be helpful in following the treatment.

The measurements which have received greatest attention in clinical shock are those which suggest alterations in blood volume. The *blood hemoglobin* and *hematocrit* are simple and *accurate measurements of the relative* concentration of red cells and plasma in a given sample of blood. They are not measurements of blood volume

Assumptions about blood volume based upon them may be in error for two reasons. The sampled large-vessel hematocrit in shock may be considerably higher than the total blood (body) hematocrit Second, the red cell mass and plasma volume which create the hematocrit may vary independently in either direction In spite of this, the hemoglobin and hematocrit are useful in following the replacement of acute blood losses In *situations in which knowledge* of blood volume is important, the red cell volume and plasma volume must be determined independently [6]

The laboratory findings early in shock depend largely upon the causative trauma.[7] Thus the *hemoglobin and hematocrit may* be high (burn), normal (early hemorrhage, myo-

[6] The techniques used for these determinations must make allowance for prolonged mixing time of the circulating blood in shock.

[7] The examples given in this paragraph are not intended to represent invariable findings but rather to indicate a variety of mechanisms

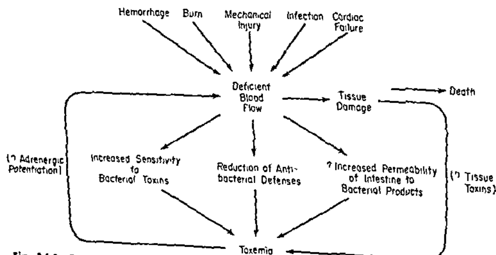

Fig 14-1. Concept of lethal mechanism in shock based upon experimental evidence.

cardial infarction), or low (hemorrhage). The *white blood count* may be high (infection, hemorrhage, myocardial infarction) or low (overwhelming toxemia). The *circulating red cell volume* may be high (polycythemia, epinephrine effect on depots), normal (myocardial infarction, certain infections, early second-degree burns), or low (hemorrhage, certain infections, later burns). The *circulating plasma volume* may be high (myocardial infarction with congestive failure, therapy induced), normal (certain infections), or low (the situation in most shock states).

Measurements of the basic defects in shock of any cause, viz., decreased oxygenation of mixed venous blood and decreased cardiac output, have not been used widely in patients. Simple and safe methods are emerging and will be helpful in solving diagnostic problems and in guiding therapy.

Blood chemistries confirm the failure of hepatic and renal function, indicate the existence of an anaerobic catabolic state, and give evidence of the loss of intracellular components (including certain enzymes [8])

COMPLICATIONS AND PROGNOSIS

The serious complications of shock may be listed in four categories: (1) *Acute hypoxia* of critical areas Sudden fatality during severe insufficiency of peripheral blood flow is usually due to *myocardial infarction* (especially common in the presence of preexisting coronary artery disease) or *brain stem damage* (failure of respiratory or circulatory centers) (2) *Thrombosis of critical vessels.* The lower extremity arteries, the cerebral arteries, or the mesenteric arteries or veins may thrombose (3) *Acute renal insufficiency.* Lower nephron nephrosis may result from either brief and severe or prolonged and moderate depression of renal blood flow. (4) *Shock refractory to therapy.* This may be due to the elaboration of a toxic factor, as suggested by experimental studies

The prognosis of shock depends upon the general condition of the patient prior to shock, the nature and severity of the precipitating cause, the occurrence of serious complications, and the development of irreversibility due to prolonged generalized tissue hypoxia. The clinical impression of unresponsiveness should never deter the physician from continued aggressive therapeutic efforts. More than one patient considered to have an "irreversible" condition is now living and well.

TREATMENT

Every minute saved in the early recognition and treatment of shock is worth hours of last-ditch heroics. Once begun, treatment must be thoroughly effective in order to prevent the progressive and often insidious deterioration which results in unresponsiveness to any and all therapeutic measures. In the presence of profound circulatory collapse, the attending physician must act rapidly [9] to prevent a lethal complication (e g., myocardial infarction, cerebral accident, or lower nephron nephrosis). Emergency resuscitative measures must include *rapid restoration of deficient blood volume* (the magnitude of the deficiency is often underestimated and may approach 50 per cent of the normal volume), *immediate control of continuing hemorrhage,* and the institution of *pressor therapy* if collapse persists in the absence of evidence of hypovolemia. After the vital signs have been restored to reasonable values there is time for a more thorough evaluation of the factors responsible for the deficient peripheral blood flow in the given individual

Is there a persisting deficiency of circulating blood volume? This is often the case and is suggested by the clinical facts (hemorrhage, large burns, extensive tissue trauma, gastrointestinal losses, chronic malnutrition), by direct measurements of red cell and plasma volume, and by therapeutic trial One must learn to

[8] The demonstration of a marked increase in *serum lactic dehydrogenase* and of *transaminase* in experimental shock (Vesell et al.) indicates the need for caution in diagnosing myocardial infarction on the basis of a serum transaminase rise when shock may be responsible.

[9] In this circumstance there is no time to wait for a surgeon, for elaborate instrument kits, or even for sterile instruments, unless these are immediately available. Remember that the brain cannot tolerate severe anoxia for more than a minute or two. If a superficial vein is not easily found for venipuncture (try the external jugular vein, which will usually fill if compressed above the clavicle), expose an upper extremity vein and insert a large cannula or plastic tube for administration of whole blood, blood fractions, or pressor drugs as indicated Type "O," Rh-negative blood is useful while awaiting cross matching.

treat the patient and not the laboratory data (Moore). The patient in congestive heart failure or in certain types of septic shock (e.g., peritonitis) may not tolerate the rapid restoration of a "normal" blood volume, hematocrit, serum sodium concentration, etc. *Pulmonary edema* may intervene. One should be guided by the pulse, respiration (including frequent pulmonary auscultation for early evidence of edema), arterial pressure, sensorium, skin temperature, and urine flow (an in-dwelling catheter for hourly output observations is often indicated). *If urine formation is insufficient (less than about 0.5 ml/min), this indicates persisting shock* (decreased renal blood flow) unless there is preexisting or concurrent renal damage. The latter possibility may be tested, without risk of seriously overloading the circulation, by the rapid infusion of 500 ml of 5 per cent glucose in water. A transient rise in the rate of urine formation will demonstrate persisting blood volume deficiency. No rise will suggest renal damage and the need to avoid overhydration.

The pressor drug *norepinephrine* (noradrenaline, levarterenol) may be lifesaving if shock persists in the face of a relatively normal blood volume. If the blood volume is deficient, a normal arterial pressure induced by pressor drugs may offer false security in the presence of a persisting inadequacy of peripheral blood flow. In experimental normovolemic shock, the drug effects a marked increase in cerebral, coronary,[10] and adrenal blood flow rate. The hepatic flow is unchanged. The renal blood flow is decreased. Cardiac output may or may not be increased. Norepinephrine should be administered as a constant intravenous drip in relatively low concentrations (4 to 8 ml *Levophed*[11] per liter) and via an inlying plastic tube. This will minimize the possibility of extravascular infiltration, which causes serious necrosis of skin and subcutaneous tissues. The infusion rate should be adjusted so as to maintain a reasonable arterial pressure. If increasing amounts of the drug are required, the physician should try to stabilize at a lower arterial pressure, which will be acceptable if the patient is alert, comfortable, and forming urine.[12] If this is not possible, persisting hypovolemia or untreated infection should be suspected. When the drug is no longer needed, the infusion should be terminated gradually in order to avoid significant hypotension.

There are two major facts about *infection in shock:* (1) in the presence of uncontrolled infection, even though apparently mild, *no treatment overlooking the infection is likely to succeed;* (2) sepsis may be difficult or impossible to recognize once shock has supervened. This is because the usual clinical evidences (fever, leucocytosis, pain) may be *completely masked by shock.*[13] Furthermore, shock may be the initial and only evidence of major infection. Therefore, a high index of suspicion is essential. Chests, abdomens, wounds, blood, urine, sputum, and other possibly infected areas must be investigated and appropriate surgery and antibiotics introduced early. Experimental evidence suggests the desirability of administering nonabsorbable intestinal antibiotics to all patients in shock to minimize the absorption of bacterial products from the intestinal lumen. The experimental value of the antiadrenergic drug, *dibenamine,* in the prevention of death due to transient occlusion of the arterial blood supply of the intestine (Shapiro et al.) suggests the need for clinical evaluation of this drug in clinical shock and in intestinal infarction.

Sedatives and narcotics must be used skillfully, if at all, to relieve pain and apprehension. There are increased sensitivity to and decreased elimination of these drugs in shock. They may aggravate shock by decreasing cardiac output. Small test doses are advisable. The necessary medication is best given intravenously to avoid the possibility of faulty absorption from ischemic tissues.

It is no longer considered advisable to apply extra blankets to warm the cold skin of the patient in shock. This may aggravate the shock state by countering surface vasoconstriction and enlarging the total vascular bed, thus diminishing available blood flow to more critical

[10] Isolated bovine coronary arteries dilate in response to this drug (Oppelt).

areas. The value of body cooling on the other hand remains to be more thoroughly studied.

If shock is unresponsive to volume replacement, pressor therapy, and treatment of infection, the use of *adrenal cortical steroids* should be considered. A clinical course of prolonged or severe physical strain, an electrolyte disturbance consistent with cortical insufficiency, an eosinophil count which is not severely depressed may favor this decision. Individual case reports suggest the value of such therapy even in the presence of obvious sepsis (Ebert) and even though experimental and recent clinical studies do not demonstrate cortical insufficiency in shock (Frank, H. A., et al., 1955a; Kass).

Glucose (at least 150 Gm/day) should be administered intravenously, in continuous or divided doses to prevent hypoglycemia and spare body proteins Water-soluble vitamins (B and C) should be given in large doses

Special Aspects of Cardiogenic Shock. The commonest shock-producing event of cardiac origin is *myocardial infarction* When shock accompanies this disorder, the prognosis is ominous. If the infarction is "silent," early diagnosis may be difficult and important because excessive blood or fluid therapy may easily provoke pulmonary edema In the absence of congestive failure, the *central venous pressure is thought to be low, as in other forms of shock* (Gootnick et al) The blood volume is apt to be close to normal, although slightly decreased plasma volume and slight hemoconcentration have been reported (Stead et al) If the infarction is secondary to blood loss, replacement transfusions are clearly indicated to improve coronary and general peripheral flow The value of transfusions during normovolemic cardiogenic shock is not so certain, although there may be some benefit from slow, small transfusions (Epstein et al.). It may be advantageous to administer *red cells*, instead of whole blood, to minimize the production of pulmonary edema while providing increased oxygen transport and possibly also an increased plasma volume at the expense of extravascular fluid (Moore et al). The use of arterial instead of venous transfusions has been advised by some (Page) to effect an increased arterial pressure and increased coronary flow before the increased cardiac work load must be met The clinical advantage of this approach is not established but seems questionable.[14]

If shock and pulmonary edema coexist, the physician is often in the difficult position of accepting the former or aggravating the latter The choice must always be made in favor of the treatment of the shock, however, because failure to do so is uniformly fatal. Here the physician must be in constant attendance to evaluate the severity of pulmonary edema, the sensorium, the urine flow, and the need for narcotics and sedatives, cardiac drugs, transfusions, limb tourniquets, pressor drugs, etc., in a situation of rapidly changing responses (For treatment of Pulmonary Edema associated with shock, see Part 18, Chap. 14.)

In recent years, there has been general agreement as to the great value of *norepinephrine* in the treatment of shock secondary to myocardial infarction. The experimental demonstration of a manifold increase in coronary and cerebral blood flow in response to this drug is confirmatory (Frank, E. D., et al, 1956) Fortunately, the negative effect of this agent upon renal blood flow and urine formation in the dog is not seen commonly in man, nevertheless it must be watched for (Moyer et al.). Necessary precautions in the use of norepinephrine are described above.

The value of a *high oxygen content* in the inspired air needs no comment but is secondary in importance to the restoration of peripheral blood flow. The use of drugs to improve cardiac function is described elsewhere (Part 19). One must be mindful of the danger of digitalis intoxication during potassium diuresis in successfully treated shock

In the over-all management of cardiac disease, two therapy-induced shock states deserve brief comment One is *the use of acidifying diuretics (e g , ammonium chloride)* in the presence of renal insufficiency (inability to form an acid urine) This may precipitate acute acidosis, oliguria, acute respiratory distress, and circulatory collapse. The other shock state results from *severe, chronic restriction of sodium* in the diet (under 200 mg daily). This may produce the *low-salt syndrome* (anorexia,

[14] Projected clinical research includes efforts to bypass the heart and the lungs during cardiogenic shock by using extracorporeal pumps and oxygenators

vomiting, weakness), adrenal cortical exhaustion, vitamin B depletion (low protein intake), oliguria, and circulatory collapse.

A detailed description of the treatment of shock-induced lower nephron nephrosis is beyond the scope of this chapter. Management is based upon avoidance of overhydration, provision of calories (5 to 25 per cent glucose intravenously) to minimize protein catabolism, and careful observation for serious sequelae (potassium intoxication, acidosis, tetany, pulmonary edema, central nervous system irritability followed by depression) which may indicate the need for peritoneal irrigation or kidney dialysis through the use of the so-called "artificial kidney."

METABOLIC ASPECTS OF SHOCK

The term "shock" has been used to embrace a number of seemingly similar states induced by a wide variety of agents and conditions. It cannot be defined in precise terms. A precarious state of the circulation is a central factor; there is insufficient blood flow and return, resulting in variable and inadequate nourishment (in its broadest sense) of organs and tissues. This impairment is characteristically correctable in an early stage but later becomes "irreversible," *i.e.*, refractory to current therapeutic measures. The specific physiologic and metabolic disturbances which may determine "irreversibility" (and thus death from shock despite treatment) are not yet known.

Much of the information regarding the metabolism of shock has been obtained from animal experimentation, the shock having been produced by various methods and under diverse conditions. Many of the controversial and often contradictory findings may be reconciled through consideration of these variables.

The shock syndrome is the result of a noxious stimulus, the direct effects of this stimulus, and, most importantly, the reactions of the organism to it. The nature, extent, and persistence of these reactions depend upon (1) the preshock physiologic status of the organism, (2) the nature, intensity, and duration of the noxious stimulus, and (3) the promptness of the removal of the stimulus. The correction of the immediate damaging effects of the stimulus and the rapid application of the best available local and systemic resuscitative measures are clearly important.

Ingle (1951) has emphasized that species, heredity, sex, age, nutritional status, diet, previous exposure, emotionality, activity, and bacterial pattern are some of "the extrinsic and intrinsic variables which affect the nature and extent of metabolic adjustment." He has called these variables ". . . 'heteropoietic' for, when they change in value, they tend to cause differences in metabolic responses."

In addition to the problem of *heteropoietic variables*, one must take into account the shock-inducing procedures themselves, and the assortment of arbitrary criteria used for recognizing the existence of shock. These procedures and criteria determine, to a large extent, which metabolic alterations will occur at a particular "stage" of shock, and which metabolic alterations the experimenter will recognize as signs of a fatal or favorable eventual outcome.

Hypoxia is a common feature of shock, irrespective of the type of initiating stimulus; inadequate circulation is its basic cause, curtailment of oxygen and nutrient delivery are its main features. In addition, as a result of *diminished* venous blood flow and probable diminished lymphatic flow (except from areas directly traumatized), there is an "*accumulation*" of various metabolites. These may affect the local tissue circulation and metabolism and also, by being carried elsewhere, the metabolism and circulation of other areas. Profound metabolic changes result. Effects of *hypoxia* manifest themselves earlier in some tissues than in others. *The sequence is probably due to varying susceptibility of different tissues to oxygen deficiency*, to the pattern of *compensatory circulatory adjustment*, and to *redistribution of blood flow*. In addition, a developing inability of tissues to use oxygen would further contribute to metabolic abnormalities. The vascular compensatory activities compromise particularly the circulation to the kidneys and certain *splanchnic* viscera. The requirements for immediate survival of the organism are met by sacrifice of function of some of its parts;

once the crisis is over, however, impairment of organ function may be permanent and result in death.

A general pattern of metabolic changes seems to be characteristic of, but not necessarily specific for, the shock syndrome. It involves proteins, carbohydrates, fats, water, vitamins, endocrines, and electrolytes; the response is dynamic, with an ever-changing but generally predictable pattern.

The *early metabolic responses of shock* are generally indistinguishable from the pattern of reactions that results from other stresses, some of these early biochemical alterations may be spontaneously reversible if the injury is not severe, or may be readily corrected by prompt and suitable therapy. The biochemical alterations that occur as shock progresses have, for the most part, not been identified as anything other than the results of the hypoxia that accompanies persistent deficiency in blood flow. Furthermore, none of these alterations has as yet been unequivocably linked to the lethality of shock.

Some of the usual features of the metabolic changes in shock are decreased oxygen consumption and body temperature, hyperglycemia, lactacidemia, pyruvicacidemia, impaired glucose tolerance, acidosis, increased breakdown of certain tissue proteins, *azotemia*, retention of sodium, chloride, and water, and an abrupt drop in blood ascorbic acid. These changes are usually accompanied by involution of lymphoid tissue and thymus, lymphopenia and eosinopenia, leucocytosis, increased pituitary-adrenal activity with associated depletion of adrenocortical cholesterol and ascorbic acid, and an increase in some blood adrenal hormones, both medullary and cortical The concentration of antidiuretic hormone in the blood is also greater. Liver function is impaired, as evidenced by an increase in Bromsulfalein retention, a decrease in the rate of conjugation of certain adrenal steroids, a decreased ability of the liver to synthesize glycogen, to deaminate certain amino acids, and to build urea.

All metabolites are interrelated, and in the final analysis, all must be considered together The forthcoming separate characterization of the behavior of the metabolites in shock is arbitrary and has been adopted only in order to facilitate exposition.

WATER AND ELECTROLYTES

A clear distinction must be made between the effect of the injury and that of shock. Sudden serious disturbances of water, electrolytes, and plasma proteins may result directly from the initial injury, independently of and not as a consequence of shock, in fact, these changes may be the primary initiators of certain forms of shock, e.g., burn. It has been known for a long time that the early movement of blood constituents into, adjacent to, and from the injured area may lead to fatal depletion of water, electrolytes, and protein, if adequate replacement therapy is provided, death may be averted. After injury, blood volume is generally low, interstitial space is variable, depending primarily on the nature and extent of the blood plasma and fluid losses. Plasma sodium and chloride concentrations may be normal or low, while plasma potassium is normal or slightly high. There is a shift of sodium into injured cells, with a concomitant outward flow of potassium and hydrogen ion Sodium and chloride excretions are initially low, that of potassium is high These changes in urinary electrolyte excretion seem to reflect primarily the changes in fluid and electrolyte distribution in the injured animal, there may be also direct hormonal influences on the kidney, such as may result from increased adrenal cortical activity (aldosterone?) and increased antidiuretic hormone activity. If shock supervenes, *urine output slows or stops*, and sweating, vomiting, abdominal distention, and diarrhea may occur, sodium enters cells and potassium leaves, resulting in hyponatremia and hyperpotassemia These electrolyte shifts occur not only in injured areas, but also generally and may result from the tissue hypoxia of shock Plasma potassium may also rise as a result of cellular release of potassium associated with the net breakdown of tissue protein and glycogen The untreated shocked animal becomes increasingly sensitive to extracellular potassium, even though the hyperpotassemia is usually quantitatively small during shock; however, concentrations sufficient to cause death are frequently encountered near death. The toxic effects of potassium may be accentuated by hyponatremia or hypocalcemia Plasma magnesium concentration may rise in peripheral circulatory failure

In shock, *blood volume is decreased*, since the fluid influx into injured areas comes mainly from the blood. *In the absence of hemorrhage*, this decrease is principally *of the plasma*, but there are also fluid and electrolyte shifts from uninjured areas resulting in their *dehydration*. The specific quantitative electrolyte and fluid changes of the various organs and tissues are incompletely known

There is a slackening of transcapillary water movement as measured by D_2O [the symbol for "heavy water" (deuterium oxide)], this is interpreted as due primarily to a decrease in functional capillary area Present evidence indicates that there is no generalized increase in capillary permeability in shock; only the capillaries in the injured area definitely "leak," though *in some species*, late in severe shock, the capillaries of the intestinal tract and heart are congested, bleed, and may be abnormally permeable There is no clear evidence to suggest that these changes stem from alterations in endocrine function.

(Rosenthal, S M, et al)

PROTEINS

Present evidence best supports the idea of a dynamic interchange of most body constituents Borsook and Keighley are generally considered the originators of this concept; Schoenheimer, Whipple, their coworkers, and others developed the picture of *a dynamic steady state among body proteins* in adults This thesis rests on the existence of three possible continuing processes. (1) proteins are completely degraded into amino acids, which are then resynthesized into new proteins, (2) proteins could be partially degraded to peptides, which would then be reassembled into different proteins, and (3) synthesis of certain proteins could occur by transformation of existing proteins Only the existence of the first process has firm support to date.

Schoenheimer, Rittenberg, and associates demonstrated with labeled amino acids that the structures of most proteins are not fixed, but that their constituent amino acids are undergoing interchanges with the free amino acids of their environment. The *rate of* interchange varies with the protein involved In order to maintain this apparent steady state, there must be a very precise balance between protein synthesis and degradation.

This steady state is altered during shock so that there is an increased breakdown of body protein. The specific mechanisms underlying this change have not been fully defined—some are local and perhaps unique to areas directly damaged by the initiating trauma; others are general and seemingly similar for a wide variety of injuries. While the over-all systemic metabolic reaction to injury results in a net increase of total tissue catabolism over total tissue anabolism, each tissue presumably metabolizes in its own fashion, and there may be strikingly different net anabolic and catabolic rates among various tissues in shock (Cuthbertson). Unfortunately, the pattern consequent to shock is incompletely known.

Plasma protein concentrations may change in shock (particularly in shock caused by traumas and burns), not only because of the shifts and losses of water and electrolytes already described, but also because of shifts and losses of the plasma proteins themselves Plasma protein may be lost directly from the site of injury (e g, from superficially burned areas) or by hemorrhage, or it may be temporarily sequestered in injured areas. As shock progresses, plasma protein which at first had entered and left the injured areas rapidly, now exchanges *more slowly*, and its reentry into the lymph or blood is delayed In untreated hemorrhagic shock, *mild hypoproteinemia* develops as a result of the plasma loss and its partial replacement by protein-poor extravascular fluid, the decreases of albumin and globulin are proportionate In contrast, plasma albumin drops disproportionately in severely burned or wounded subjects, this results from the faster passage of albumin through the directly damaged capillaries.

Plasma prothrombin and fibrinogen fall in severe shock; there is usually an accompanying increase in fibrinolytic and other proteolytic activities Properdin may decrease abruptly, the significance of this is not established.

Rises in plasma nonprotein nitrogen are almost constant accompaniments of severe shock; the over-all increased tissue protein breakdown and the oliguria characteristic of shock combine to lead to the elevated concentrations of most of the plasma nonprotein nitrogen (NPN) components, e g, urea, creatinine, uric acid, and amino nitrogen Generally, these increases are proportional to the severity of the initial

injury and the severity of the succeeding shock state.

The behavior of *amino acids* in shock has received special attention during recent years, because of the central role of the amino acids in the metabolism of proteins and in the interrelationships among proteins, carbohydrates, and fats.

Postulates of amino acid "pools" have been put on an experimental basis by the use of isotope experiments, and studies by Campbell et al., Miller et al., and Borsook et al. have shown that in rats, rabbits, and mice, plasma amino acids have an extremely rapid turnover rate—of the order of minutes. The plasma amino acid levels might be subject to at least the following influences: food intake, intestinal absorption, transcapillary and transcellular exchange, deamination, transamination, decarboxylation, interchange among amino acids, protein, carbohydrates, and fats, and renal excretion and reabsorption

The plasma amino acids in normal individuals are relatively unchanged from day to day except for the effects of diet Any wide fluctuations unrelated to feeding assume great significance—they indicate, probably, a basic upset in the body economy.

Increases in the plasma concentration of the total free amino nitrogen are characteristically observed in severe shock (Sayers, M A, et al., Engel et al, 1943). This increase may begin early and then rise progressively as shock becomes more profound and prolonged Indeed, Sayers and associates found that an early rise in plasma amino nitrogen during the initial 1 hr of bleeding used by them to initiate hemorrhagic shock in rats meant death for these animals if untreated, while similarly bled and untreated rats without the early rise in amino nitrogen lived. However, even marked rises in plasma amino nitrogen had no adverse prognostic significance if appropriate transfusion therapy was given

Though *renal dysfunction* is a constant accompaniment of severe shock, it can play only a secondary role in aminoacidemia (Rosen et al., 1958).

The rate and degree of plasma amino nitrogen elevation vary with the type of shock. They are greater if direct tissue damage is present (tourniquet, crush, burns). There is evidence that amino compounds are "produced" in disproportionately large amounts in the injured areas and, in these types of shock, account for the earliest increases which may precede the onset of hypotension. Later, as other organs become "damaged" as a result of the reduced circulation, there is a more generalized tissue contribution of plasma amino compounds. The increased release of amino acids from certain peripheral tissues (e g, muscle) of the shocked animal presumably reflects an increased protein breakdown to protein synthesis ratio, a change in the normal steady state. Late in severe shock not only do amino compounds enter the plasma in increased amounts, but their "removal" from the plasma by the liver may be slowed Liver slices from rats in hemorrhagic shock deaminate amino acids and form urea slowly; similarly, the ability of liver slices from burned rats to deaminate alanine is impaired This may be because of *hepatic hypoxia* (Engel et al., 1944); arrest of the circulation to the liver of rats in vivo leads to progressive failure of the liver to remove amino acids from the blood. Shocked dogs, though, retain the ability to clear certain amino acids injected intravenously in large amounts; Seligman and associates (1948) interpret this to mean that the amino acidemia of shock represents *deficient blood flow to the liver* rather than specific impairment of liver function per se.

Unfortunately, most of the information regarding plasma amino compounds in shock derives from studies in which only total amino nitrogen concentration has been measured by one or more colorimetric methods not wholly specific for amino acids In a few investigations, the more specific gasometric ninhydrin method has been used, but it also yields information only about the behavior of the twenty-odd amino acids lumped together When 19 amino compounds were measured individually by an ion exchange chromatographic technique in ultrafiltrates of plasma and serum from normal and untreated severely burned rats (80 per cent mortality in 12 hr), the free amino nitrogen rise was not proportionate among the individual amino compounds In fact, about three-quarters of the rise was accounted for by an increase in taurine and a newly found amino conjugate fraction (Rosen et al, 1953) Asparagine, isoleucine, leucine, tyrosine, phenylalanine, and histidine were also increased, while proline and valine were decreased The amino conjugate fraction rose fourfold (proportionate to the plasma NPN and urea), its composition was similar in the normal

and unburned rats—glutamic acid and glycine were predominant; alanine, proline, serine, threonine, valine, and leucine were present in lesser amounts

Very little information is available in man, and that available is difficult to interpret, since the patients studied had undergone many severe stresses which might influence plasma amino acid levels. These stresses included the initial severe wounding (complicated and variable), hemorrhage, shock, anesthesia, operation, fluid and electrolyte imbalance, fever, infection, antibiotics, and intravenous infusions (blood, albumin, gelatin, etc.). During shock, as in the case of rats, no general increase in the plasma amino acids of these patients occurred—alanine, in particular, phenylalanine, tyrosine, lysine, and taurine were usually increased; isoleucine, proline, and glycine were decreased (Levenson et al). In patients with severe liver disease, but not shock, methionine, tyrosine, and phenylalanine are most commonly elevated.

Various hormones affect amino acid metabolism and, thereby, the levels of the plasma amino acids. Noall and coworkers, using a nonmetabolizable amino acid as a "tracer," have recently presented evidence suggesting that many hormones modify the rate of transport of amino acids across cell membranes But what roles the various hormones play in the changes of plasma amino acids in shock is not known Increase in plasma amino nitrogen follows administration of large doses of certain adrenal hormones, but an intact pituitary-adrenal system is not essential for the aminoacidemia seen in burned rats. Although injection of insulin will lower the concentration of amino nitrogen in the plasma, the amount of insulin required is enough to produce signs and symptoms of hypoglycemia

Elevations in blood ammonia concentration are commonly observed late in shock, but so far as is known, significant toxicity therefrom almost never occurs, except in patients with serious liver disorders and severe gastrointestinal bleeding. The rise in ammonia stems, in part, from a decreased ability of the liver (rat) to form urea (Engel et al , 1946)

CARBOHYDRATES

Claude Bernard (1877) is credited with being the first to indicate that hemorrhage produces hyperglycemia. This observation has subsequently been confirmed in various species and with different shock-inducing procedures, illnesses, and injuries.

Neuroendocrine mechanisms which mobilize the cellular stores of carbohydrate are activated by trauma, giving rise to *a prompt increase of blood glucose before shock is evident. Hyperglycemia* usually persists into advanced shock until the terminal stages, when blood glucose may fall to subnormal levels, especially when environmental temperature is high (Trusler et al.).

In hemorrhagic shock, hyperglycemia is accompanied by *an increase in blood lactate and pyruvate levels,* which continue to rise concomitantly with liver and muscle glycogen depletion as shock progresses (Haist, 1946). The metabolism of glucose by the peripheral tissues may be greatly increased early. There is ultimately a proportionately greater increase in lactic acid, resulting in an elevated lactate/pyruvate ratio which may reflect a predominance of anaerobic over aerobic carbohydrate metabolism, intravascular glycolysis as a consequence of prolonged hypoxemia has also been held accountable for this change.

Preinjury liver glycogen depletion, adrenal demedullation, adrenalectomy, evisceration (hepatectomy), or occlusion of the afferent and efferent blood flow of the liver not only prevent the postinjury rise in blood glucose but usually result in hypoglycemia Although the processes of carbohydrate mobilization are highly complex and incompletely known or understood, it is generally agreed that hepatic glycogenolysis, presumably by epinephrine that is reflexly released, is chiefly responsible for the early hyperglycemia Other evidence suggests that, in addition, nervous stimuli and blood-flow alterations may act directly on the liver and thereby influence glycogen breakdown. Glucocorticoids inhibit peripheral utilization of glucose and promote gluconeogenesis and glycogenesis However, the hyperglycemic response occurs after trauma of the adrenalectomized animal that is maintained on saline solution and DOCA and fed, or instead, fasted and given a fixed dose of corticoid that alone does not alter the blood glucose level (Engel *et al*, 1937) (See page 14-32 for further discussion of interpretation of this sort of experiment) New formation of carbohydrate from lactate, pyruvate, and possibly amino acids deriving from peripheral tissues helps maintain the hyperglycemia as the glycogen stores are be-

ing depleted; this is likely, since a sustained hyperglycemia occurs in the prefasted but otherwise normal rat after hemorrhage. There is the further possibility that under certain conditions the peripheral utilization of glucose may be inhibited by both corticoids and epinephrine.

The *hypoglycemia* that develops later in shock is generally considered a result of a depletion of liver and muscle glycogen, the absence or reduction of gluconeogenesis and glycogen formation and the often-mentioned increased glucose metabolism by the peripheral tissues underlie these depletions. The importance of this last factor is demonstrated by the finding that hemorrhage results in a very rapid fall of blood sugar in adrenodemedullated eviscerated rats.

Dogs in late oligemic shock have elevated blood levels of pyruvate and lactate with an increase in the lactate/pyruvate ratio. Reinfusion of the shed blood is followed by a prompt return of these constituents to normal levels whether or not animals subsequently die. Blood-clearance studies of lactate, pyruvate, or glucose injected during hemorrhagic hypotension (Lamson bottle technique) indicate that these dogs clear the blood lactate essentially as well as nonhemorrhaged dogs, but the clearance of pyruvate is somewhat below normal and that of glucose is markedly reduced. When the blood is returned, the blood clearances of glucose and pyruvate return to normal. These observations may signify that the piling up of these metabolites during hemorrhagic shock may result from poor blood flow and that a critical hepatic enzymatic derangement is not involved (Seligman et al., 1947). However, some experiments with rats suggest that impairment in liver function does occur late in hemorrhagic shock. The evidence of how glucose is utilized by the peripheral tissues in shock is still controversial.

As already mentioned, the precise role of the *adrenal hormones* and their intimate interrelationship with other hormones after injury and shock are unknown. After hemorrhage, adrenalectomized dogs have an elevation of blood lactate and pyruvate, as do intact animals, but the blood glucose level falls, unlike the response of normal dogs, blood lactate and pyruvate remain elevated after transfusion, possibly because of the absence of corticoids and the gluconeogenesis which they support. Continuous intravenous infusion of epinephrine into normal dogs results in changes of blood lactic and pyruvic acids that are not so marked as those occurring after hemorrhagic shock. These observations suggest that the alterations of blood lactic and pyruvic acids in hemorrhagic shock are not solely attributable to epinephrine or corticosteroids, and are not necessarily correlated with the blood glucose level. The possible participation of *glucagon* (the pancreatic hyperglycemic factor) in the glycemic response has not been evaluated, nor is there presently any quantitative information on the sequential alterations of growth hormone activity during shock.

During the induction of *limb ischemia*, i.e., while the occlusive device is in place, there is a rise in blood sugar, lactate, and pyruvate which is ascribed to *sympathetic stimulation* from the pressure of occlusion; following tourniquet release and the development of shock, a marked further increase in these blood constituents and an increase in the lactate/pyruvate ratio occurs (Haist et al., 1944). The sudden increase in lactate is, in part, attributable to its release from the hypoxic limbs. The hyperglycemia after tourniquet release is ascribed to the liberation of epinephrine. As shock progresses, the hyperglycemia is sustained, while, for the most part, the lactate/pyruvate ratio does not deviate markedly from normal. Terminally, blood lactate accumulates again as the blood sugar falls to subnormal levels.

Tourniquet shock results in a reduction of the glycogen stores of the liver and the muscles of the uninjured as well as the injured extremities, depletion of glycogen with shock occurs whether or not the animals have been fasted, and is greater than that found in fasted normal animals or in animals with the tourniquets in place. Tourniquet-shock animals have a reduced tolerance for administered glucose, which correlates with the duration of limb ischemia and their inability to store glycogen in liver and muscle even on insulin administration, which, however, lowers the blood sugar. The later fall of blood glucose in the shocked animals, below that of control animals, while the liver and muscle stores of glycogen are being depleted suggests that carbohydrate is not being formed from noncarbohydrate sources or that greater amounts of sugar are being metabolized peripherally, or that both these factors are involved. Since exogenous insulin reduces blood sugar in the shocked animal, the presence of hyperglycemia suggests that during shock, either the blood sugar level is not regulating endogenous insulin secretion, or normal insulin activity may be deranged or blocked.

(Stoner et al., 1952a.)

FATS

Little is known of fat metabolism in shock Engel and Hewson found that the fasting ketosis of rats anesthetized with Nembutal is promptly suppressed by mild hemorrhage Severe hemorrhagic shock (associated with a rise in plasma amino nitrogen concentration) results in a progressive hypoketonemia and an inhibition of a rise in blood ketones following infusions of sodium octanoate These same changes were noted in adrenalectomized rats (maintained on DOCA and saline solution) subjected to hemorrhagic hypotension and shock Engel and Hewsin point out that these findings may be due to either a depressed hepatic production of ketone bodies or an accelerated utilization by the peripheral tissues, or both The hepatic production of ketones may be depressed because of impaired delivery of ketone precursors to the liver secondary to reduced hepatic blood flow or to impaired oxidation of fatty acids by the liver.

Adrenal cortical lipids (total and cholesterol) decrease rapidly in domesticated rats subjected to hemorrhage, tourniquet, burn, and traumatic shock Coincidentally, there is a drop in adrenal ascorbic acid In many feral species, these changes do not occur, nor do they in domesticated rats adapted, by repeated exposures, to the stressor (Woods). Increases in certain serum lipoproteins, cholesterol, and lipid phosphorus follow many types of injuries in which tissues are directly damaged–but these changes are not consequent to shock

NEUROENDOCRINE FACTORS

Some evidence has already been cited that certain of the metabolic reactions to injury and shock may be mediated through the neuroendocrine system Early impetus for this view came from the observations and writings of Claude Bernard, Cannon, and Selye The state of adrenal function was noted to influence profoundly the capacity of the organism to respond to injury An abrupt increase in adrenal medullary activity following injury was demonstrated early Later, Selye reported tissue disintegration, cellular atrophy, and even necrosis in various tissues, with the notable exception of the adrenal cortex, which, on the contrary, almost invariably hypertrophied. *These changes in the adrenal glands have since been correlated with an early increased secretion of certain adrenal hormones, medullary and cortical (e.g., aldosterone, hydrocortisone, epinephrine, and norepinephrine)*. Many manifestations of the usual reactions to injury were not found in adrenalectomized animals. It was further noted that the resistance of adrenalectomized animals to exogenous stressors is low; this confirmed what clinicians had long known about patients with Addison's disease.

A relationship between the pituitary and adrenal glands in these physiologic responses was demonstrated in the early studies. It was known that adrenal cortical atrophy occurred following hypophysectomy and that hypophysectomy, like adrenalectomy, prevents the usual reactions to stressing stimuli. Extension of these observations led Selye to formulate his concept of the *general adaptation syndrome*. Later observations showed that ablation or stimulation of certain areas of the hypothalamus either depress or activate the secretion of ACTH There has been much discussion about how the hypothalamic-pituitary-adrenal system is activated, nervous, metabolic, and circulatory factors are involved (see Part 2, Chap 30).

After injury, certain hormones are apparently secreted in amounts capable of causing metabolic upsets when given in situations of no stress. Further, many of the biochemical responses to injury seem to be related to the presence of an injury of a certain severity rather than to one of a specific type, and in this sense, seem nonspecific Since many of these metabolic changes are similar to those induced by administration of certain pituitary and adrenal hormones, increase in central nervous system, hypothalamic, pituitary, and adrenal activity has been considered important in the development of the metabolic reaction to injury This thesis has gained some support from the findings that (1) many of these changes do not occur in the unsupported adrenalectomized animal, and (2) some of the metabolic changes and the apparently increased adrenal hormone secretion roughly parallel the severity of the injury

The precise manner in which hormones modify metabolic reactions is not known. It seems clear that they do not initiate new reactions.

Biochemical studies of cell fractions have revealed that metabolic sequences are more or less restricted to certain discrete structural units within

the cell; i.e., the ultrastructural and spatial organization may be of importance in the regulation of metabolic processes in the cell. This is particularly evident when the tissue slice or intact mitochondria is required to observe certain reactions. It is believed that the hormones may primarily influence cellular metabolism at this "enzyme-structure level" ("cytoskeleton" of Peters) instead of at the "enzyme level," the classical, more "primitive" method of control in which the vitamins, antimetabolites, and enzyme inhibitors apparently exert their influence on metabolism, and the level at which substrate and enzyme competition and the pure "biochemical lesion" are operative (Rossiter).

Cori stated that "although phosphorylase has been implicated in the metabolic action of epinephrine, hexokinase in that of insulin, and oxidative phosphorylation in that of thyroxine, none of these systems is sufficiently well understood to make one confident that the results obtained so far explain the actions of these hormones."

It is generally accepted that there is an association between the extent of metabolic response to injury and shock and the level of adrenal hormones secreted. The level of adrenal hormones necessary in adrenalectomized animals for the full metabolic reaction depends on the severity of the injury.

"The adrenal cortical steroids and the epinephrines appear to operate largely as a functional unit physiologically. The multiple sites of action and character of tissue and organ responses to the two species of hormones are strikingly similar Many actions attributed to the steroids may be ascribed, in effect, to action of the epinephrines Many actions of the epinephrines are not elicited in the absence of steroids. Corticoids and neurohumors are not interchangeable, however Steroids maintain the integrity and responsiveness of tissues in the process of reacting to the epinephrines This relationship is best seen on exposure to stress, when the defect of steroid lack may be elicited by heightened sympathetic-medullary activity In the absence of the corticoids, responses to the neurohumors are progressively lost, while the destructive symptoms of adrenal insufficiency are progressively exhibited" (Ramey and Goldstein).

Certain studies have demonstrated the occurrence of some of the biochemical changes associated with injury in the presumed absence of any concomitant increase in adrenal hormone production.

Ingle et al. and Toby and Noble found the same increase in urinary nitrogen excretion following fractures in adrenalectomized rats on maintenance adrenal cortical extract and in sham-operated controls, no increase was found in adrenalectomized rats maintained on saline solution. Similar observations of the occurrence of hyperglycemia in traumatic shock (Selye et al, 1941) have been made

Ingle concluded that the negative nitrogen balance resulting from injury requires the presence of adrenocortical hormones but is not specifically caused by an increase in their secretion. Ingle calls this the "permissive" or "supporting" action of the adrenocortical hormones, and Selye, from a different point of view, speaks of the "conditioning" action of these hormones. Certain responses to the adrenal steroids are modified by associated systemic stress. This may result from a decrease in "inactivation" of circulating steroids by the liver or a change in target-tissue reactivity. Further, the possibility exists that in adrenalectomized animals kept on maintenance doses of adrenal hormones, accessory adrenal tissue may respond to trauma with increased activity. Clarification of these points will have to await the measurement of steroid activity and secretion in injured animals. It should also be pointed out that the particular response to injury which appears to be similar for the normal and the corticoid-maintained-adrenalectomized animal may be based on different metabolic mechanisms. The metabolic and functional significance of the increased levels of corticoids (hypercorticalism) after injury of the *intact animal* remains unclarified.

Considerably less information is available regarding the behavior of the other endocrine glands after injury and in shock. There is an *increased secretion of antidiuretic hormone (ADH)*, which doubtless affects renal function (Mirsky et al.). ADH liberation may be one of the mechanisms by which the secretion of ACTH is stimulated.

While the presence of active *thyroid hormone* seems necessary for the usual metabolic response to injury, knowledge of the behavior of the thyroid in shock is extremely limited.

Hamolsky et al reported an early progressive, but reversible, disturbance in the uptake of I^{131} by the thyroid of rats in tourniquet shock. Conversion to organic-bound iodine was slowed, reversibly, late in shock. They point out that these observations may represent either an increased or decreased thyroid activity. Similar changes were noted in tourniquet-shocked rats which had been adrenalectomized 3 weeks earlier and maintained on sodium chloride postoperatively.

One of the factors which obtunds generalization from experimental work to man *is the* wide species variation in hormone synthesis, secretion, excretion, and metabolism. *Furthermore*, the relationship between in vitro and in vivo hormone and gland studies is not always *clear*. The effects of extensive surgical procedures which are often required in in vivo endocrine studies also raise many questions An additional complication is the incomplete knowledge as to the effects of conjugation on the biologic activity of hormones, such that bioassay cannot equate a loss of potency with "inactivation." On the other hand, chemical quantitation may not describe the biologic activity of the material in question.

Finally, the orderliness of metabolism and activity of unicellular organisms, which (as far as is known) do not possess the counterparts of neurons or endocrines, should not be forgotten If, further, the fact is considered that an animal, properly cared for, may progressively adapt to the deficiencies created by ablation of portions of its nervous or endocrine faculties, its behavior and appearance seeming to be normal if the animal is not exposed to emergency situations, it becomes clear that "control" and "adaptive" modalities in higher organisms ultimately reside not in the highly specialized transmission and mediation systems (as they appear to under emergency situations), but in the peripheral tissues, more precisely, their cells and their "primitive" control mechanisms. In the higher organism, the regulatory influences of these keystones of homeostasis are abetted but masked by the superincumbent actions of the hormones and neurohumors (Levine, 1953, Krebs, 1955–1956) However, it has been amply demonstrated that the nervous and endocrine systems serve as "buffers" during emergency situations, functioning amidst reciprocal *interrelationships* to attenuate the latitude of adaptive *reactions*. (Selye, 1950, Ingle, 1951, Harris)

BIOLOGIC ENERGY TRANSFORMATIONS

The realization that the contribution of a burn or wound to an *ensuing* shock process is dynamic and protracted has led to much speculation and study on the nature of possible local factors, other than fluid and electrolyte shifts and losses, that might arise from regions of direct or secondary tissue damage and could cause adverse systemic effects, hastening the process to a fatal conclusion. It is somewhat *ironic* that an extract of skeletal muscle that on injection was reported (Green and Bielschowsky; Green, 1943) to reproduce the signs and symptoms of tourniquet shock, should ultimately prove to have its most deleterious activity ascribable to adenosine triphosphate (ATP).

ATP is one of the prime movers of normal biologic processes It is the chief energy carrier between energy-yielding catabolic reactions and the energy-requiring needs of cells. The aerobic energy-yielding metabolism of carbohydrates, fats, and proteins results in a coupled synthesis of ATP from inorganic orthophosphate and ADP (adenosine diphosphate), the *utilization* of ATP results in its breakdown to inorganic phosphorus and ADP. Intimately connected is the *creatine-phosphocreatinine* reaction (see Part 2, Chaps. 1 and 2)

The important role of ATP as an energy source on the one hand, and the evidence that "toxic" products from damaged or ischemic tissues might represent ATP or its breakdown products on the other, have led to studies which have examined both aspects in shock. Whether or not physiologically significant changes in plasma nucleotide concentrations occur in shock is still *uncertain*

Threlfall and Stoner (1957), who have been among the active investigators of this subject, have recently *stated* that "the absence of significant amounts of pharmacologically active nucleotides and their derivatives from the *blood* of the rat after limb ischemia helps *to* supply a negative answer to the question—do the adenine nucleotides play any part *in* the causation of the general responses to injury."

Hoffman et al., using a combined enzymatic and spectrophotometric *method* for determining ATP, ADP, and AMP (adenosine monophosphate), have assessed *these* adenine compounds in the blood of *patients* in various kinds of shock No significant changes in the blood levels of these compounds were found, nor were they detected in the serum. However, alterations *in the* ultraviolet absorption spectrum of the blood filtrates suggested that there was an increase in the blood level of a substance *closely related to the adenine* nucleotides, the addition *of* sodium inosine monophosphate to normal blood gave an abnormal spectrum exactly comparable to that found *in*

the cell; i.e., the ultrastructural and spatial organization may be of importance in the regulation of metabolic processes in the cell. This is particularly evident when the tissue slice or intact mitochondria is required to observe certain reactions. It is believed that the hormones may primarily influence cellular metabolism at this "enzyme-structure level" ("cytoskeleton" of Peters) instead of at the "enzyme level," the classical, more "primitive" method of control in which the vitamins, antimetabolites, and enzyme inhibitors apparently exert their influence on metabolism, and the level at which substrate and enzyme competition and the pure "biochemical lesion" are operative (Rossiter).

Cori stated that "although phosphorylase has been implicated in the metabolic action of epinephrine, hexokinase in that of insulin, and oxidative phosphorylation in that of thyroxine, none of these systems is sufficiently well understood to make one confident that the results obtained so far explain the actions of these hormones."

It is generally accepted that there is an association between the extent of metabolic response to injury and shock and the level of adrenal hormones secreted. The level of adrenal hormones necessary in adrenalectomized animals for the full metabolic reaction depends on the severity of the injury.

"The adrenal cortical steroids and the epinephrines appear to operate largely as a functional unit physiologically. However, it has been amply demonstrated that the nervous and endocrine systems serve as "buffers" during emergency situations, functioning amidst reciprocal interrelationships to attenuate the latitude of adaptive reactions (Selye 1950, Ingle, 1951; Harris.)

BIOLOGIC ENERGY TRANSFORMATIONS

The realization that the contribution of a burn or wound to an ensuing shock process is dynamic and protracted has led to much speculation and study on the nature of possible local factors, other than fluid and electrolyte shifts and losses, that might arise from regions of direct or secondary tissue damage and could cause adverse systemic effects, hastening the process to a fatal conclusion. It is somewhat ironic that an extract of skeletal muscle that on injection was reported (Green and Bielschowsky; Green, 1943) to reproduce the signs and symptoms of tourniquet shock, should ultimately prove to have its most deleterious activity ascribable to adenosine triphosphate (ATP).

ATP is one of the prime movers of normal biologic processes It is the chief energy carrier between energy-yielding catabolic reactions and the energy-requiring needs of cells. The aerobic energy-yielding metabolism of carbohydrates, fats, and proteins results in a coupled synthesis of ATP from inorganic orthophosphate and ADP (adenosine diphosphate); the utilization of ATP results in its breakdown to inorganic phosphorus and ADP. Intimately connected is the creatine-phosphocreatinine reaction (see Part 2, Chaps. 1 and 2).

The important role of ATP as an energy source on the one hand, and the evidence that "toxic" products from damaged or ischemic tissues might represent ATP or its breakdown products on the other, have led to studies which have examined both aspects in shock. Whether or not physiologically *significant* changes in plasma nucleotide concentrations occur in shock is still uncertain.

Threlfall and Stoner (1957), who have been among the active investigators of this subject, have recently stated that "the absence of significant amounts of pharmacologically active nucleotides and their derivatives from the blood of the rat after limb ischemia helps to supply a negative answer to the question—do the adenine nucleotides play any part in the causation of the general responses to injury."

Hoffman et al, using a combined enzymatic and spectrophotometric method for determining ATP, ADP, and AMP (adenosine monophosphate), have assessed these adenine compounds in the blood of patients in various kinds of shock. No significant changes in the blood levels of these compounds were found, nor were they detected in the serum However, alterations in the ultraviolet absorption spectrum of the blood filtrates suggested that there was an increase in the blood level of a substance closely related to the adenine nucleotides, the addition of sodium inosine monophosphate to normal blood gave an abnormal spectrum exactly comparable to that found in

patients with severe shock. Others have found some increases in plasma uric acid concentrations in shock

Measurements of muscle ATP contents have shown significant decreases in the directly damaged muscles in conditions such as tourniquet shock, but the evidence is controversial regarding other muscles of shocked animals. Following limb ischemia in rats, it has been found that the restoration of energy-rich phosphate levels in muscle appears to depend not only on the duration of ischemia, but also on the degree to which circulation is restored following release of occlusion. If the limb is ischemic for more than 2 hr, inorganic phosphate and nucleotide disappear from the damaged muscle Although the fate of the nucleotide has not been established, it is believed that it is released from the muscle as inosine monophosphate (Threlfall et al, 1957). This would appear to tie in with the observations already mentioned of the abnormal ultraviolet absorption spectrums (possibly ascribable to inosine) of blood filtrates of patients in shock

Extensive investigations were performed on biologic energy transformations in hemorrhagic, tourniquet, and Noble-Collip drum shock in rats (McShan et al., LePage) They found generally decreased tissue levels of high-energy phosphate compounds and energy-yielding substrates, they also noted increased blood levels of certain pentoses, inorganic phosphorus, and products of protein and carbohydrate catabolism Following hemorrhage in rats, the liver and kidneys seemed to be most affected, whereas brain, heart, and skeletal muscle energy stores were less affected, the changes in Noble-Collip drum shock were comparable to that of hemorrhage, but those following tourniquet shock were less severe

They interpreted their data as consistent with their hypothesis that *the state of shock, in general, involves a critical depletion of energy reservoirs (ATP and phosphocreatine)* Depending on the type of shock (*initiating* cause), they hypothesized that there may be *either a primary breakdown (as by "overwhelming stimulation," e.g, Noble-Collip drum shock), a failure of resynthesis of high-energy compounds (hemorrhage), or a combination of both (tourniquet shock).*

During *hemorrhagic shock* in dogs, the "high-energy phosphate" content of liver is found to decrease. However, the extent of the decrease does not correlate with the ultimate response (favorable or unfavorable) of the dog to transfusion of the shed blood (Rosenbaum et al.). Whether or not dogs survive following transfusion, the hepatic pyrophosphate level is rebuilt to the extent that arterial pressure has improved at the time the liver sample is taken. These findings are in general agreement with those previously mentioned regarding the rapid restoration of normal blood levels of lactate, pyruvate, and amino acid metabolism following transfusion after oligemic shock in dogs.

It has been suggested that the generalized depletion of energy-yielding compounds, if present, results either from an "uncoupling" of oxidation from phosphorylation (i.e, failure to synthesize "high-energy" bonds while carbohydrates, etc., are still being broken down) or from an incomplete metabolism of carbohydrate. However, Stoner et al. (1952b), found that when an uncoupling agent—dinitro-*o*-cresol—is injected into rats, there result chemical and physiologic effects unlike those of tourniquet shock. Regarding the theory of incomplete breakdown of carbohydrate, there are insufficient data on hand from studies of various forms of shock to draw definite conclusions Although it is tempting to speculate that there is a "block" in carbohydrate catabolism between the glycolytic and tricarboxylic acid cycles in view of the reported unique increase in glucose-6-phosphate in undamaged muscle of rats in tourniquet shock, this might only reflect the generalized increased rate of carbohydrate breakdown (Threlfall et al., 1954).

Judging from the injection of a wide spectrum of tissue metabolites (potassium, magnesium, calcium, inorganic phosphate, adenine, adenosine, adenylic acid, ATP, histamine, tyramine, and acetylcholine), Tabor and Rosenthal felt it unlikely that the temperature fall observed following tourniquet release is due to the release of these materials into the circulation in shock. Although magnesium and ATP can lower body temperature, the amounts required apparently exceed those present in the tissues Several other studies (Stoner et al, 1954, Coranson et al.) have not supported the generalized "energy-depletion" hypothesis of shock.

Limb ischemia (tourniquet) in rats kept in a room at about 20°C did not cause significant changes in the energy-rich phosphate concentration of muscle outside the damaged area; turnover rates of ATP and phosphocreatine were not altered significantly outside the damaged limbs Stoner and Threlfall felt that the fall in body

temperature decreases the energy demand, resulting in a temporary balance between production and utilization of energy-rich bonds which allows the animal to survive for an extended period of time. However, at higher environmental temperatures, 30°C, a generalized tissue depletion of high-energy materials was found during fatal limb ischemia Stoner and Threlfall suggested that the elevated environmental temperature prevents the fall in body temperature that usually ensues in tourniquet shock, and as a consequence, energy production is not so severely depressed However, the energy requirement appears to be disproportionately increased, since survival time is shortened and the decrease in tissue high-energy phosphorus is exaggerated.

The findings to date, primarily because of limitations of technique, have neither proved nor disproved the possibility that depletion of energy stores of certain vital cells might be responsible for death from shock
(Green et al, 1954.)

OXYGEN CONSUMPTION, ACID-BASE BALANCE, ENZYMES, AND VITAMINS

Oxygen consumption is generally lowered in severe shock This reflects primarily the slowed blood flow, the tissues apparently do not lose their ability to use oxygen until the terminal stage However, functional and anatomic deterioration may set in before oxygen consumption fails quantitatively (as judged principally by in vitro studies) This has been demonstrated for dog brain by Rosenthal, O, et al (1945).

Consequent to the inadequate oxygen and nutrient delivery and slowed venous blood flow in shock, a *metabolic acidosis* results, there are a decrease in blood pH, carbon dioxide, and bicarbonate contents, and increases in pyruvate, lactate, phosphate, and sulfate Pulmonary ventilation or diffusion changes may alter this pattern, at times a *respiratory alkalosis with hypoxemia* may result *Renal blood flow is sharply curtailed*, and urinary output slows and finally stops, thereby, the regulating effects of the kidneys on acid-base balance are lost to the severely shocked individual

The liver has been the most frequently studied tissue in shock Considerable disagreement exists as to whether liver respiration is increased or decreased in shock Most of the information derives from in vitro studies However, many of the apparent differences are reconcilable when consideration is given to the details of the individual experiments and the type of shock procedure used.

An explanation for some of the apparently conflicting findings is offered by Hannon and Cook. They subjected rats to either tourniquet or hemorrhagic shock and demonstrated that liver taken during the "terminal stages of shock" could have either high or low rates of oxygen consumption, depending on the preshock nutritional state of the animal. They confirmed the work of Fuhrman and Field by demonstrating that a depletion of liver glycogen by fasting the normal animal results in an apparent increase in in vitro liver oxygen consumption, as was the case when liver glycogen depletion resulted (presumably from hypoxia) following tourniquet, freezing, or burn shock in the previously well-fed rat. However, they point out that "the observed Q_{O_2} for shocked tissue is not comparable with the normal tissue since the methods of calculation do not take into account the increment of weight added to the normal tissue (or subtracted from the shocked tissue) by the glycogen present" When this is accounted for, no differences are noted between the livers of the controls or shocked animals except when the shocked rats had been deprived of water and food for 24 to 30 hr. They conclude: "We may now regard shock as being either of no influence or conducive to a reduction in respiration, this effect being primarily referable to the stagnant anoxia occurring in the liver. The degree of reduction, if any, would in turn be determined by the severity of the anoxia together with the magnitude of the initial energy stores." They suggest that a structural or chemical derangement in the mitochondria of liver tissue (secondary to hepatic hypoxia and an ensuing depletion of high energy phosphate) may be the basis for certain of the observed biochemical changes

Wiggers has found in his studies of experimental hemorrhagic shock in dogs that despite evidence of compensatory mechanisms which tend to support coronary circulation, *myocardial depression ("deterioration of myocardial expulsive power") may occur during oligemia, which may contribute to the progressive circulatory failure at this time*, while transfusions prove to be of temporary benefit only These findings were based primarily on cardiac pressure and volume curves He made it clear that although his evidence suggested that myocardial depression is a "frequent and important complication," it might not be a factor in all

states of shock, and its severity would be conditioned by the variations in the preshock functional status of the myocardium (muscle and vessels) of patients or experimental animals.

Bing emphasized that the normal, relatively low coronary flow (8 per cent of the cardiac output) is counterbalanced by the maximal myocardial oxygen extraction. He points out that *in hemorrhagic shock, the fall in oxygen usage by the heart is due not to reduction of myocardial oxygen extraction but to the reduction in coronary flow*

The observations of Edwards et al. suggest that *hypoxia of the heart,* apparently unlike that of other organs, results in an increased extraction (utilization is not changed because of the reduced coronary blood flow in shock) of lactate; this suggests that the enzymatic pathways for lactate metabolism are not deranged consequent to the myocardial ischemia of hemorrhagic shock. The tendency toward negative myocardial glucose and pyruvate balances suggests that there may be a block in their metabolism Although the investigators did not measure cocarboxylase (phosphorylated thiamin), they suggested that dephosphorylation of the latter, which has been reported to occur in various tissues (other than the heart) in hemorrhagic shock and anoxic anoxia by Grieg and Govier, may be the primary factor preventing pyruvate catabolism via the tricarboxylic acid cycle. However, this hypothesis, at the same time, renders the fate of myocardial lactate uncertain, since its catabolism via this pathway would likewise be blocked.

Strawitz and Hift found that the mitochondria of hearts, livers, and kidneys from dogs in hemorrhagic shock differed in size and shape from those of normal dogs. Heart mitochondria, isolated by differential centrifugation, from the shocked dog retained the normal oxidative capacities for Krebs cycle substrates. However, in the presence of the hexokinase system (which imposes a constant extramitochondrial demand for ATP) heart mitochondria from the shocked dogs manifested impaired oxidative capacities The latter led the author to make an interesting suggestion "It is possible that the classical Warburg methods, which supply an optimal environment as far as cofactors and substrate requirements are concerned, obscure or reverse early enzymatic defects."

There is a surprising lack of information on the metabolism of the various water- and fat-soluble *vitamins* in shock, and of the enzymes for which some of these vitamins in modified form are cofactors (coenzymes). That information which is available is conflicting and rife with uncertainty. The possible derangement of vitamin and enzyme functions (coenzyme, apoenzyme, or both) consequent to the hypoxia and related sequelae of shock, and its possible early relevance to the metabolic responses already detailed, are clearly of fundamental interest—thiamin, pantothenic acid, pyridoxine, nicotinamide, and riboflavin are functionally interrelated in hormone, carbohydrate, lipid, and amino acid metabolism, and in cellular respiration (hydrogen carriers). The inadequacy or cumbersomeness of the analytic methods used and the prevalent uncertainties of the specific actions of and requirements for the various vitamins in the normal individual, to say nothing of the injured person, probably have been the primary deterrents to their intensive investigation in shock "That symptoms of vitamin deficiency result from partial failure of one or more metabolic functions for which the missing vitamin is essential is a truism It is an interesting commentary on the present state of our knowledge, therefore, that in almost no instance is it possible in higher animals to correlate the presence of a given symptom of vitamin deficiency with hypofunction of a known enzymatic reaction for which that vitamin is essential Until this becomes possible, our knowledge of the relationship of these bodily catalysts to physiological function is incomplete" (Snell).

Soon after shock there is an abrupt and often sustained drop in blood and urinary *ascorbic acid,* and an apparent decrease in tissue ascorbic acid saturation, as judged by "load tests" In the rat, ACTH-stimulated secretion of ascorbic acid from the adrenal gland into the adrenal venous effluent precedes the release of corticosterone, the ascorbic acid discharged by the adrenal gland can be quantitatively recovered from the adrenal venous effluent (Slusher et al.). The basis for the lowered tissue saturation and plasma content of ascorbic acid is not known

Many shock studies have been performed with ascorbic acid pretreatment. Whereas guinea pigs (which, like man, require a dietary source of vitamin C) that were pretreated with large doses of ascorbic acid before being subjected to a standardized hemorrhagic shock procedure showed a significant increase in survival rate (de Pasqualini), no beneficial effects were noted in ascorbic acid–primed rats subjected to hemorrhagic shock

(Sayers, G., et al., 1945). Ascorbic acid given to mice after the release of tourniquets also had no significant effect on survival (Millican et al.)

Certain vitamins may be active only when combined as *coenzymes*. This implies that a plethora of "free" vitamins does not exclude a possible deficiency of coenzyme It also seems reasonable that the hypoxia and hyponutrition of the tissues in shock may result in a "functional" derangement and altered metabolism of certain *enzymes* and enzyme systems Furthermore, known ionic imbalances (specifically required metallic ions), pH, and fluid shifts may contribute to enzymic alterations during shock.

Lamson et al. were brought to the problem of studying certain coenzymes and their associated vitamins in shock by their earlier findings of liver glycogen depletion and the inability of insulin to alter the glycogenolysis and hyperglycemia of shocked dogs They were aware of the carbohydrate disturbances accompanying thiamine deficiency and a reported effectiveness of thiamine therapy in severely burned patients Dogs were subjected to fractional hemorrhage to a low level of arterial pressure with no replacement therapy, generally, control dogs died in 3 to 4 hr from the start of bleeding It is unfortunate that these experiments were not supplemented by other types of hemorrhagic shock procedures, particularly those with reinfusion of the shed blood These workers first found that thiamine administration results in a fall in blood pyruvate (keto acids) and an increase of both the blood pressure and survival times They next found that the pyrophosphate ester of thiamine, cocarboxylase, was being dephosphorylated in skeletal muscle, duodenum, and liver, chiefly in the former two tissues However, while Alexander, who studied the free and phosphorylated (total) thiamine content of dog liver and muscle under different experimental conditions of hemorrhage, found a decrease of muscle cocarboxylase, he found, on the contrary, an increase in total and phosphorylated thiamine in the liver (Alexander's dogs were given extra thiamine for 2 to 4 days prior to bleeding) Greig further found that vitamin-containing coenzymes, such as cozymase (nicotinamide) and alloxazine adenine dinucleotide (riboflavin), were decreased in brain, muscle, and liver (in this order) after hemorrhage, more consistent reductions being observed with cozymase, and that the apoenzymes were also possibly being inactivated, since in vitro studies indicated that the apoenzymes of lactic dehydrogenase and amino acid oxidase were destroyed under anaerobic conditions

Although the relationship between in vitro and in vivo studies is not always apparent, it has been demonstrated that, in contrast to the above findings, the addition of thiamine or cocarboxylase to a homogenate of brain tissue after hypoxia did not result in improvement of the decarboxylation of pyruvate. This was taken to indicate that *neither destruction of the respiratory enzymes nor a critical deficiency of coenzymes is a primary result of hypoxia* (Rosenthal, O., et al.). Increased *proteolytic* and *fibrinolytic* activity in the blood and plasma of animals and patients may occur when shock is severe and prolonged; the physiologic significance of these changes is not known.

Shorr et al have demonstrated that two humoral vasotropic principles, one *a vasoexcitor material* (VEM) and the other *a vasodepressor material* (VDM), appear in successive order during experimental hemorrhagic, traumatic (Noble-Collip drum), and tourniquet shock.

The presence of these materials was recognized by a bioassay technique which involves the microscopic detection of a VDM or VEM response of the terminal vascular bed of the mesentery of the rat's mesoappendix to topically applied epinephrine after intravenous injection of the test material, usually blood or incubation medium. The appearance (titer) of these vasotropic factors in the blood of shocked animals has been temporally correlated with direct visual observations of the successive hyper- (compensatory stage) and hyporeactive (decompensatory stage) phases of the terminal vascular bed of the mesentery.

TOXINS, TOXEMIA, AND INFECTION

Cannon and Bayliss and Dale et al. (1918) presented evidence that shock following muscle injury might be due to the absorption of one or more toxic substances formed in the injured muscle *The toxin theory of shock,* with its implied humoral vector, has remained a most provocative subject. Certain investigators have not been deterred from espousing the idea that a single "toxic" factor may be the *cause* or the *predominant cause* of shock, hoping to find a simple preventive or cure for shock However, present awareness of the multietiologic nature of the shock syndrome and its variable complex of possible sustaining and perpetuating factors, which are often clinically recognizable,

has provoked the statement that ". . . the search for a simple method of treating shock is akin to the search for the fountain of youth —it is a phantasma" (Moyer, C. A., 1953).

The nature of VEM, which appears very early in shock and which derives from the hypoxic kidney, is unknown; its vasoexcitor property, however, can be abolished in vitro by liver or kidney tissue. Prolonged hypoxia renders the kidney incapable of producing VEM further, and for this reason, it may cease to appear in the blood late in shock. VDM has been identified as a form of *ferritin*, an iron-containing protein normally found in many tissues (primarily liver, spleen, skeletal muscle, and duodenal mucosa), that has vasodepressor activity, which property can be inactivated aerobically or activated anaerobically in vitro by liver tissue. It is believed that the prolonged hypoxia of shock also results in its release in vivo, peak titers are noted during the decompensatory stage. Its persistence in the blood is believed to result from the progressive hypoxic deterioration of the poorly characterized liver-inactivating mechanism.

Some reports question the importance of VDM in the shock syndrome (Hampton et al ; Frank, H. A., et al , 1952b) However, there is presently no decisive evidence that VDM is or is not causally related to the "irreversibility" of shock. Shorr's colleagues are currently pursuing the study of the metabolism of ferritin, and the activation and inactivation of its vasodepressor properties by liver parenchymal and reticuloendothelial cells (Baez et al.). The *reticuloendothelial system* has recently gained new prominence in its apparent relationship to the shock syndrome, but the nature and details of its participation are yet to come.

A most interesting and unique finding is the ability of the liver of Noble-Collip drum–tolerant animals to inactivate VDM aerobically in vitro after it has previously been exposed for 2 hr of anoxia in vitro, which regularly destroys the inactivating capabilities of normal rat liver (Zweifach et al , 1951) *Tolerance* was established by subjecting the animals to graded and repeated episodes of trauma, they thereby became resistant to ordinarily lethal doses of such trauma Such animals exhibit certain metabolic changes during the training regimen, e g , decreased liver glycogen and decreased body fat (Chytil et al.), and may have a cross tolerance for other types of trauma, e.g , hemorrhage. Following exposure to trauma, they manifest biochemical changes of tissue and blood that are qualitatively similar to those of nonadapted animals, but, in contrast to the latter, the rate and degree of these alterations, in general, are not so great, and, most importantly, they tend to be restored to normal more quickly

Further exploration of the mysteries of adaptation to injury and shock are in order and are needed before any description of mechanisms can safely be made.

There is some evidence that animals have a lowered resistance to infection and an increased susceptibility to injected endotoxins in the early period after severe injury, particularly if shock is present or has occurred The mechanisms for these alterations in sensitivity are not yet known. An abrupt drop in the serum properdin level and some alterations in reticuloendothelial function have been noted, as well as the numerous metabolic changes already described. Dubos, describing some of his observations of experimental infection in animals subjected to abrupt changes in dietary intake, has stated:

> It is likely that disturbances in the general state of health often bring about qualitative and quantitative changes in the biochemical characteristics of the inflammatory area. These in turn may interfere with the processes which control the activities of micro-organisms within the lesion As a result, the response of the body to infection and consequently the micro-environment in which the infectious process follows its course, are under the control of factors which may be metabolic or psychic in origin. This concept accounts in part for the fact that susceptibility to infection can change independently of the immunological state of the infected individual. Since changes in susceptibility can occur rapidly, and be extremely transient the intensity of exposure to an infectious agent may be less decisive than the physiological state of the exposed individual, determining whether infection fails to take hold, becomes established, runs an abortive course, or evolves into overt diseases.

If fulminating infection develops in the injured patient or animal, shock may thereby be induced or, if present, intensified, e g , the severe circulatory failure secondary to the toxemia of clostridial wound infections. But what of the possibility of toxemias not so patently present?

Fine and coworkers have submitted a large

body of experimentation on several species and forms of shock, especially shock irreversible to blood transfusion, which they are satisfied indicates that a toxic humoral factor, viz., a bacterial endotoxin deriving from the bacteria of the gut, plays a predominant, if not exclusive, role in determining the lethality of shock They have demonstrated to their satisfaction that blood or Seitz-filtered plasma of animals (rabbits and dogs) dying of irreversible hemorrhagic shock can kill suitably sensitized recipient animals, but not normal animals, on parenteral injection (Fine, Schweinburg et al., 1951) These findings are as yet uncorroborated One of the authors of this chapter (Einheber) has not been able to find toxicity in the blood of dogs and rabbits dying of irreversible hemorrhagic shock or of rabbits dying in a shocklike state following temporary occlusion of the superior mesenteric artery (see Shock in General, earlier in this chapter).

CONCLUSION

Some factors clearly involved in the metabolic changes associated with shock have been discussed, and some of the limited information regarding their pertinence has been presented Unfortunately, most of the reports have been concerned with changes in concentration of various metabolites in blood and plasma There have been few in vivo measurements of specific tissue metabolism. Interpretation of the blood chemical changes is complicated by the factor of differential circulation rates per se, superimposed on the possible changes in the metabolism of the organs or tissues involved Since many of the qualitative biochemical alterations found in shock are likewise observed after injury *without* shock, the precise significance of these alterations as regards the ultimate fate of the individual are incompletely known and remain largely speculative The same holds true for the basic mechanisms responsible for the evolution and progression of these alterations. At the same time, one should not lose sight of those metabolites which seemingly are not altered "Thus we might assume as a working hypothesis, that whatever variable is held most constant is the key to natural physiologic regulation The wisdom of the body is such that by the time a steady state is reached, under new demands, the important variable, the one with survival value, is regulated within physiologic limits" (Hamilton).

At present, it would seem, as Engel wrote (1953),

> that a variety of metabolic changes eventuate as a result of the hypoxia of circulatory failure, and that in general these reflect a shift to an anaerobic type of metabolism, with consequent decrease in efficiency in terms of energy yield. This latter fact in itself might be considered as the most important consequence of the initial hypoxia, and if uncorrected might be expected to lead to increasing deterioration of many essential systems and functions which are dependent on a continuing energy supply. At what point these summated changes and energy deficits become critical remains to be established

In determining the pertinence of various observations, particularly with a view to establishing their role in the lethality of the shock state, the following should be considered: If the correction of a trauma-induced "deficiency" (excluding obviation of positive deleterious factors at injury) is attempted some time after injury and results in the survival of the animal, then it is important to be able to recognize the stage after injury when a particular animal or a majority of animals in a group will no longer respond to such corrective measures, assuming that the effectiveness of such measures is shown, in general, to diminish with the time elapsing after the initiation of injury, e g, blood transfusion in hemorrhagic shock If such a prediction of lethal outcome cannot reliably be made because of inadequate objective criteria or because replacement therapy is not attempted or is inadequate, or the animal dies or is sacrificed prematurely, then the death of the traumatized animal or the associated phenomena studied (observed manifestations) may be due to a deficiency of the effective therapeutic agent (e g, whole blood, plasma, or electrolytes), or to such a deficiency plus its consequences (i e, those derangements no longer remedied by replacement therapy as judged by death).

The authors have high hopes that new approaches to "shock problems," made possible by the use of some of the recently developed scientific techniques and the recognition of the induction of resistance to noxae by "conditioning," will provide some answers to fundamental questions which plague physicians and researchers today.

Arteriosclerosis

J. LINZBACH

Lobstein (1833) coined the word *arteriosclerosis* for the changes consisting of thickening and induration of the layers of the arterial wall Histologically it is possible to observe completely different morphological changes in the affected arterial walls. There are hyperplastic, degenerative, thesaurismotic, necrotic, inflammatory, and organizing productive processes that can occur in any combination (Wolffe et al, 1952)

During the intervening time, it has been found impossible to determine a common pathogenetic explanation for the different morphological observations or to distinguish certain types of arteriosclerosis etiologically, pathogenetically, or morphologically unless certain inflammatory and degenerative arterial diseases were taken into consideration

Almost every case differs from others by quantitative, qualitative, and local variations One extreme is formed by cases of so-called *diffuse arteriosclerosis* in which it is sometimes possible to study the complete morphology of arteriosclerosis The other is represented by cases in which a single, isolated plaque, located on the intima of a coronary vessel and weighing only a few milligrams, is responsible for death This variability and the "focal" character of the disease indicate different pathogenetic mechanisms acting during life, among which are physical and chemical properties of the vascular wall and of the blood In spite of the fact that most people die from the effects of arteriosclerosis, the mechanism of this disease is still unknown. All the pathogenetic theories on human arteriosclerosis are based upon either experiments with animals, or circumstantial evidence from morphological observations A pathogenetic hypothesis has to consider that arteriosclerosis (1) is focal; (2) increases with age, (3) is combined with various morphological changes; (4) has a predilection for determined points of the same vessel, (5) is found in men earlier than in women, (6) is found more commonly and at an earlier age in strong, muscular persons, (7) is accelerated by high blood pressure, (8) is promoted by certain metabolic disturbances (see also experimental arteriosclerosis); (9) occurs during infectious or toxic states, and (10) is very rare and of moderate degree in the pulmonary artery and in veins.

THE NORMAL ARTERIAL SYSTEM

Structure. The vessels and the heart are lined with a continuous and *uninterrupted endothelial layer* Using a light microscope it is possible to observe, in freshly fixed material from human beings, an endothelial layer in the whole aorta, the large and middle-sized arteries, and the veins [Linzbach et al, 1957 (*man*), Duff et al, 1951 (rabbit).] In fresh preparations of the aortic intima of both man and various mammalians it is possible to observe with the phase-contrast microscope that the endothelium is supported by cytoplasm at the side opposite to that of the blood stream (Fig. 15-1) For this reason fresh endothelia, consisting of only one layer of cells, have amazing strength and elasticity, and can stand a certain amount of tension (Linzbach, 1952). Even at the highest magnifications it is not possible to recognize an intercellular cementing substance which binds the endothelia to-

corresponds to the effective filtration pressure in this layer.

Functional Anatomy. The arterial wall can be compared with a combination of a car tire with and without an inner tube (Linzbach, 1958). The inner tube corresponds to the endothelium, the most internal layer of which is plastic, deformable cytoplasm, while the reticular external layer is porous (Fig. 15-1) and is supported by a plastic viscous layer (subendothelial connective tissue). The musculoelastic media corresponds to the tire and the lamina elastica interna of the muscular arteries to the inner tube, which can be distended only with difficulty.

When one considers the arterial system from this point of view, the following proportion appears While *the blood pressure decreases to one-third from the aorta to the capillaries, the diameter increases about 10,000 times* The total wall *tension must* then be 10,000 times larger than in a capillary (Burton, 1951). (Aorta *tension* = 150,000 dynes/cm; capillary *tension* = 12 dynes/cm.)

The morphological nature of the endothelium proves that the wall tension in this layer is of the same order in both the capillary and aorta In the capillaries, a blood pressure of 30 mm Hg, with a tension in the endothelial layer of 12 dynes/cm (equivalent to 12 mg/cm), is tolerated well and produces an equivalent filtration pressure in the endothelial layers, this is not possible in the arteries An endothelial tension of 12 dynes in the arteries represents only a minimal fraction of the level of blood pressure. However, the filtration pressure in the endothelium of the arteries must still be small It follows that the elastic viscous endothelium and the subendothelial connective tissue are compressed against the solid internal layers of the media by almost the entire intravascular pressure in the arteries Therefore, the hydrostatic pressure in the intima must decrease from the aorta to the periphery The exact level of this compression depends upon both the intravascular pressure and the elasticity of the internal layers of the media and of the lamina elastica interna, respectively As the intravascular pressure decreases in the arteries from the center to the periphery, a corresponding longitudinal pressure gradient must exist in the intima. This is of an order of magnitude which corresponds approximately to the decrease in pressure within the arteries Although the pressure drop, and therefore the longitudinal pressure gradient are small in comparison with the length of the arterial system, these forces are sufficient to produce, during life, a slow but constant *peripheral displacement of fluid in the intima*, i e, from the thoracic to the abdominal aorta and also within the peripheral vessels This longitudinal flow in the intima can be accelerated in the aorta by the pulsational variations in pressure.

In the capillaries, the intravascular pressure produces a high filtration pressure. *In the aorta and other arteries, on the other hand, there is high compression and low filtration pressure* The compressive force on the human aorta corresponds to a load of about fifty kilograms. As the colloid osmotic *pressure of the blood is only about* 25 mm Hg, the low filtration pressure *in the* arterial endothelium with *the endothelium* under high compression is of great *importance* to the internal tightness (Linzbach, 1958).

Although the vascular diameter increases *10,000 times, from the capillaries* to the aorta, the thickness *of the* wall increases only about 1,000 times *from* the capillaries (about 2 to 3 μ) *to the aorta* (2 to 3 mm). Consequently, the parietal tensions exerted on the wall (Eq. 3) and the density of the constituent materials *must* be 10 times greater in the tunica *externa* (tire) than in the intima (inner tube).

In agreement with Burton (1951), it is *necessary* to admit that the brunt of the tension of the arterial wall is sustained by the elastic material, with a *relative* decrease from the aorta to the periphery. The modulus of elasticity of the elastic fibers has been evaluated as 1.4×10^7 dynes/cm² by Meyer et al. (1950), while the value *obtained* from the protein content of muscle fibrils amounts only to 0.8×10^7 dynes/cm² and, considering the water content of the muscle, should be essentially *still* lower.

Nutrition of the Vascular Wall. The normal structure and function of a tissue presupposes adequate nutrition Warburg (1926) developed the concept of *critical* "layer-thickness" of tissues. This term defines the *maximum* thickness which a tissue *between* two nourishing surfaces (e g, between two capillaries) may attain so that the supply of nutrient substances

Fig. 15-1. Model of the endothelium of the human aorta. The model was sketched following studies with the electron microscope of fresh, unfixed endothelial preparations.

gether and in which metabolic changes occur (Chambers et al, 1947). However, it is not possible to demonstrate pores with the light microscope.

At the side adjacent to the blood stream, the cytoplasm of the endothelial cells forms hyaloplasmic pads of variable height which can be designated as covering plates. The borders of these plates lie closely together and form (under the phase-contrast microscope) a framework which meets with the cell boundaries and the places of silver lining (Fig. 15-1). The healthy *subendothelial connective tissue* contains fine collagen and elastic fibers. The ground substance is impregnated with acid mucopolysaccharides. Besides, there are fibrocytes, histiocytes, and monocytes (Duff et al, 1957); and also many mast cells (Sundberg, 1955), which are important in heparin formation that may play a role in the stability of the fat in the ground substance of the intima. From the physical point of view, it is possible to consider the healthy subendothelial connective tissue as a *loose, elastic viscous sponge*.

In muscular arteries there is a strongly woven, tough membrane, the *lamina elastica interna,* between the muscular *media* and the subendothelial connective tissue. It forms an elastic perforated tube, which is strengthened by lengthwise and crosswise fibers. In the cerebral arteries, the lamina elastica interna is particularly well developed. The musculoelastic media of the aorta, on the other hand, has no internal elastic membrane.

The Relationship between Blood Pressure, Elasticity, Wall Tension, Compression (Intramural Pressure), and Filtration Pressure. The intravascular blood pressure (p) in dynes per square centimeter produces a tension (F) in dynes (Fig. 15-2).

$$F = p \cdot 2r \cdot l \qquad \frac{\text{dynes}}{\text{cm}^2}\,\text{cm}\cdot\text{cm} \qquad (1)$$

where r = radius

l = length of vessel

The elasticity produces (in the wall of the vessel) a tangential tension of the wall. It is measured by the formula of Laplace as total wall tension (T_r) in dynes per centimeter along the length of vessel.

$$T_r \approx p\,\frac{2rl}{2l} = p \cdot r \qquad \frac{\text{dynes}}{\text{cm}^2}\cdot\text{cm} \qquad (2)$$

The wall tension (T) in dynes per square centimeter corresponding to the thickness of the wall of the vessel (S), has the dimensions of a pressure, and it is possible to calculate it from the elasticity (F), divided by the measure of both diameters (inner and outer) of the vascular wall (Fig. 15-2).

$$T = p\,\frac{2rl}{2dl} \approx \frac{pr}{d} \qquad \frac{\text{dyne}\cdot\text{cm}}{\text{cm}^2\ \text{cm}} \qquad (3)$$

These equations are valid only for vessels with relatively thin walls.

In arteries with thick walls consisting of multiple elastic layers, the first internal layer transforms part of the blood pressure into wall tension. Its external layer, therefore, will not be compressed against the internal surface of the second layer by the full blood pressure. As every layer absorbs part of the blood pressure in the form of wall tension, the compression of the layers of the wall will decrease *from the inside out.* The thicker the layer, the larger *is its modulus* of elasticity, and the greater the percentage of blood pressure which will be *transformed into* wall tension, with greater decrease of compression. This decrease

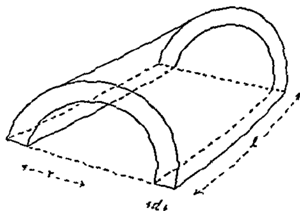

Fig. 15-2. Explanation in the text.

coronaries, others in the media, i.e., the femoral arteries (Hieronymi, 1956). In persons with hypertension, the thickening of the wall is more rapid. Focal and diffuse fibrotic thickenings of the intima occur in many arteries at very typical points without any simultaneous deposit of lipids.

EARLY CHANGES

Diffuse and Focal Lipid-free Fibrous Thickening of the Intima. The theory of gradients of pressure in different directions in the intima, caused by the intravascular pressure, can explain the formation and localization of the thickenings of the intima

1. Thickening of the intima develops more rapidly in the abdominal than in the thoracic aorta (Wilens, 1951)

Explanation: A gradient of pressure with centrifugal direction produces a slow current of filtration that causes a chronic "edema of the intima" in the abdominal aorta. This is gradually and continually transformed into the "edema-sclerosis" of Rossle (1943)

2. At the bifurcation of the aorta, there are fibrous thickenings of the intima

Explanation. The drop in blood pressure which takes place in the branches causes a displacement of the tissue fluid of the intima in the branches of the aorta.

3. In tortuous arteries, the intima is thicker at the internal than at the external part of the curves

Explanation In a curved vessel, the intravascular pressure is higher toward the outer than toward the inner border Therefore, a circular gradient of pressure is created with an accumulation of tissue fluid, followed by a proliferation of intima in the areas of minimal pressure on the inner curvature

4. At points which are pathologically narrow, as in coarctation of the aorta, there are thick, fibrous plaques on the intima

Explanation At the point of coarctation, the arterial pressure drops, however, it increases again below the stenosis The plaques form at the points of low pressure In this connection, one should also remember the formation of *endocardial plaques* from the cardiac jelly in the narrow atrioventricular canal

In spite of the fact that the thickness of the arterial walls increases continually, additional vascularization of the media can be shown in men about 30, and in women about 40 years old (Linzbach, 1944).

Qualitative Early Changes in the Intima. The so-called *lipoid spots* represent slightly elevated, yellowish, pin-point, or longitudinally striped thickening of the intima. They are found even in sucklings, especially in the intima of the thoracic aorta In young people they are usually reversible. Their formation seems to depend upon the content of fat in the diet, and subsequently of the blood (Zinserling, 1925, Bragdon, 1952, Duff et al., 1935–1954). The small foci contain fat and lipids Droplets of fat are seldom seen in the endothelium. How fat deposits in the intima from the blood and why the deposits are formed are unknown Leary's theory (1949) postulates that reticuloendothelial cells containing fat, i.e., those mobilized in the liver, are carried with the blood stream in the aorta and then penetrate through the endothelium in the intima, this has been proved wrong by isotope studies (Simonton et al., 1951) The longitudinally striped arrangement is in favor of the theory of Wilens (1942) that the fat is not only deposited at the points of entry into the intima but can wander within this structure. Presumably, the pressure gradients in the intima determine the direction of this movement The splitting and fracturing of the lamina elastica interna starts with simultaneous elastic fibrous thickening of the intima of the coronary arteries in infancy (Wolkoff, 1923, Dock, 1946; Lindsay et al., 1952, Paterson, 1952, Schornagel, 1956). After the age of twenty, fracture of the split lamina interna of the femoral arteries is also the rule (Linzbach, 1944) There is abundant mucoid material within the split lamina. The elastic fragments are often surrounded by calcium The same changes, though less marked, occur in the arteries of the arm. In the thick lamina elastica interna of the cerebral arteries the fracture begins only in the fourth decade (Wolkoff, 1933) Starting in the second decade of life, it is already possible to demonstrate an increasing deposition of acid mucopolysaccharides in the *media* together with fine, dusty calcification of the intercellular substance Loosening and fracture of the internal elastic lamina of the aorta with destruction of muscle fibers has been shown in thickenings of the intima (Taylor, 1951).

and oxygen and the elimination of products of metabolism will always be sufficient for the structural and functional requirements. The critical layer-thickness decreases proportionally as the cellular metabolism rate and the density of the cell population of a tissue increases. The meshes of the capillary network in healthy tissues are smaller than the critical layer-thickness of the tissue enclosed, in this way, a certain amount of play is guaranteed (Linzbach, 1955; Opitz et al., 1950).

Capillary-free layers are necessary for the healthy function of tissues. Such layers in parenchymatous organs have a thickness of 10 to 30 μ, in arterial walls they measure about 500 μ; and in cartilaginous tissues, about 1,000 μ. Arterial walls and cartilage are therefore thought to be tissues with slow metabolism (Burger et al, 1927). Researches on metabolism have shown that the respiration of these tissues is from one-tenth to one-twentieth that of parenchymatous tissues (Briggs et al., 1949; Kirk et al., 1954, Schutte, 1956). The greater formation of acid mucopolysaccharides in these tissues can be related to their relatively high glycolysis (Altshuler et al., 1954), and their presence seems to be a gage of the relatively low metabolic rate attributed to them (Linzbach, 1944) Arteries with walls thicker than 500 μ possess vasa vasorum. In contrast with the muscular arteries of the extremities, the wall of the human aorta, thicker than 10^3 μ, is supplied from the adventitia in the external third of the media by vasa vasorum (Ramsey, 1936–1937) Since the blood can flow into the capillary ramifications of the vasa vasorum of the aorta only if their internal pressure is greater than the compressive force on the aortic wall, it is necessary to assume that this condition obtains The internal two-thirds of the aortic wall is nourished by both the blood of the lumen and through the vasa vasorum Since the effective filtration pressure of the aortic endothelium is very low, the transfer of material through it can take place either by diffusion or active forces The filtration forces become effective only in the subendothelial connective tissue, in part radially towards the outside of the wall and in part longitudinally. The conditions obtaining in the aortic endothelium are, therefore, basically different from those in the capillary endothelium. Because of the compressive force inside the aortic wall, the effective filtration pressure at the limiting surfaces of the vasa vasorum must be small, too. As the radial filtration forces of the wall decrease from the inside out, the substances leaving the vasa vasorum can move into the internal wall layers only by diffusion. In the internal layers of the arterial wall, which are free of vessels, the total supply of nutritional substances is not determined, as in parenchymal organs, essentially by filtration, but rather by diffusion or active transferring forces, while filtration is effective only inside the wall layers The internal layers, which are free of vessels, vary in size in various species. In the giraffe, they are more than 1,000 μ in thickness (Goetz et al., 1958), but this is composed of solely elastic tissue and contains no muscle fibers, in contrast to the human aorta.

In the veins and pulmonary artery, the vasa vasorum penetrate down to the intima because, in these vessels, the mean internal pressure (and, therefore, the compression) is smaller than the mean capillary pressure of the vasa vasorum. This different structure is necessary because the supply of blood from the lumens of these vessels is definitely less than that in the arteries.

From this brief review of the normal functional anatomy of the arteries, it appears that the entire arterial system, as well as every part thereof, represents a complicated biological balance that can be altered by different causes

Development of the Arteries. In contrast to other organs and tissues, arterial walls continue to grow throughout life (Rossle et al, 1932). A few arteries grow in proportion to the weight of the heart, e g., the femorals, the coronaries, the aorta, and the pulmonary artery (Linzbach, 1944; Schoenmackers, 1949, Meyer et al., 1956, Hieronymi, 1956). The splenic artery, however, grows more rapidly than the heart, the cerebral arteries in young human beings grow more slowly. In man, corresponding arteries reach the same thickness about 10 years later in females than in males Strong and muscular men have thicker arterial walls than slim persons of the same age. In obese persons, the arteries often have thin, smooth walls (Bähr, 1938; Linzbach, 1944, Selberg, 1951). Certain arteries are most developed in the intima, i e., the aorta and the

is deposited first in the internal then in the external layers of the arteriolar walls Finally there is destruction of the wall structures, which become impregnated with lipoid material The narrowed lumen of the vessel usually has an eccentric position. A relationship between arteriolosclerosis and hypertension has been shown (Smith, 1955, 1956). The mechanism of formation of this deposit is unknown After the age of twenty the central arterioles of the spleen follicles have already been affected, while the small vessels of the trabeculae are spared In advanced age, the arterioles of kidney, pancreas, and myocardium (Wegelin, 1944; Linzbach, 1955) are affected The basal arteries of the brain show only mild changes while the middle cerebral artery and the small branches can be severely affected.

PATHOGENESIS OF ARTERIOSCLEROSIS

During the last 100 years many hypotheses about the pathogenesis of human arteriosclerosis have been proposed, some of which became a "profession of faith."

Thrombus Theory. Rokitansky (1852) explained the thickenings of the intima of the aorta as thrombotic deposits This hypothesis was reasserted in modified form by Duguid (1948) The theory is based on the observation that arterial thrombi of the wall, sometimes in the form of flat deposits of fibrin, are promptly covered by the endothelium and are incorporated in the intima, hyalinized, and organized If the thickness is sufficient, the central areas can slough off and cause the precipitation of fatty material. If arteriosclerosis is already present, *secondary thrombi* are not rare and can have an influence on the ultimate growth of the plaques, especially in the coronary arteries Lubarsch (1905) showed arterial thrombi of the wall in 22 per cent of 425 cases of arteriosclerosis However, it is unlikely that the plaques of the intima are primarily formed by thrombosis The majority of the newly formed plaques of the intima are free of disintegration products of hemoglobin In old plaques, the demonstration of fibrin and hemosiderin is not always evidence of thrombosis since they can also originate from ruptured, newly formed vasa vasorum (Muller, 1919, 1955) under the basal portion of the plaques Fibrin can also penetrate the intima from the blood (Meyer, 1949).

Inflammation Theory. Virchow designated arteriosclerosis as *endarteritis chronica deformans.* It is clear that his conception of inflammation included the degenerative processes. This hypothesis of the inflammatory cause of arteriosclerosis has been subsequently resurrected and confirmed (Klinge, 1933; Bredt, 1941; Holle, 1943; Meyer, 1949). Two different mechanisms are thought to exist.

1. Primary, toxoinfectious, and inflammatory changes of the media (rheumatic fever, infections).

2. Changes in permeability of the endothelium due to infection with resulting penetration of plasma into the intima, especially in rheumatic fever and glomerulonephritis.

The advocates of this theory cannot answer several objections, and it is unlikely that inflammation can be accepted, in general, as the cause of arteriosclerosis.

Hemodynamic Theory. This concept is impaired by the difficulty of explaining why purely physical phenomena should cause an irregular increase in the thickness of arterial walls (Muller-Mohnssen, 1957). The theory of Thoma (1911, 1922, 1923) combines several theories He considers that the primary process of arteriosclerosis is a degeneration of the media followed by dilatation of the vessel and secondary, compensatory proliferation of the intima Gradients of pressure in different directions in the intima would cause a focal proliferation of the intima

The "Wear" Theory. This theory has played an important role in research without offering a definition for "wear." Aschoff (1925, 1939) believed that certain points of the arterial system were exposed to a proportionately greater mechanical load which, in time, would produce local destruction and degeneration of the arterial walls It would be possible, with some limitations, to agree with this theory regarding the early changes in the lamina elastica interna, since these are of great importance in the biological balance of the arterial walls There is no doubt that the internal elastic layers are submitted to severe changes in tension due to changing diameter.

Aging Theory. A real predisposition to arteriosclerosis due to senility was mathematically proved by Schunz et al (1955). Burger (1939) advocated this theory and considered the increasing deposition of calcium, choleste-

The Pathogenetic Significance of the Early Changes. Arterial growth and all the aforementioned early changes, with the exception of the lipoid deposits, are not macroscopically striking but have something in common: the tissue of the wall of the arteries is eventually thickened. When the lamina elastica interna is intact, compression of the intima toward the inside is relatively high; toward the outside, low. Conversely, when the membrane is destroyed, the pressure within the intima will decrease while pressure will increase on the outside of the media. The decreasing compression in the intima favors a flow of tissue fluids from the adjacent intimal spaces in the region of minimum pressure, with the ensuing fibroelastic transformation. However, increasing pressure inside the media shifts the critical pressure to the outside until flow can occur in the vasa vasorum, so that some of the vasa vasorum are blocked. The increase of pressure in the media, after local destruction of the lamina elastica interna causes an enlargement of that part of the wall which is not supplied with blood, especially when there is a thickening of the intima.

The early and severe destruction of the internal elastic membrane of the coronary arteries due to considerable proliferation of the intima of these arteries, probably begins during youth and is favored by the flow of tissue fluids from the intima of the aorta The strongly formed lamina elastica interna of the cerebral arteries, on the other hand, guarantees high compression of the intimal space in these vessels. As there is also a thin media, these arteries are affected only at a relatively advanced age (Wolkoff, 1933).

The destruction of the internal musculoelastic layers of the media of the aorta must have the same effect as the destruction of the lamina elastica interna of muscular arteries It is not possible to discuss here the particular effects of hypertension (see Rotter, 1949) or those when the vasa vasorum are affected.

Fig. 15-3. Scale-like tightened endothelia over an arteriosclerotic calcified plaque of intima of human aorta (woman of 45). The endothelia were loosened from each other by the strong pressure of the cover glass (Ringer; electron microscope, immersion in oil). Examined 21 hr after death.

THE COMPLETE PICTURE OF ARTERIOSCLEROSIS

The typical picture of arteriosclerosis is characterized in the *aorta* and *coronary arteries* by the atheromatous plaques on the intima and relatively little involvement of the media (Marchand, 1904). The localization of the lesions usually corresponds to those points in which the early changes are also most intensive. The typical lesions are plaquelike fibrous thickenings of the intima with deposits of fat and calcium in a necrotic area below the plaques near the media. The tissues underlying the plaques can be supplied by vasa vasorum through the media. Alterations of the endothelium directly related to the formation of the plaques, have not been proved However, calcified plaques of the intima may present a secondary, scaly hardening of the endothelium (Fig. 15-3). The postmortem dissolution of hardened endothelium proceeds more slowly than that of normal tissue. The formation of giant cells can also be shown in nonarteriosclerotic areas on the endothelium of the aorta (Linzbach, 1952, Linzbach et al, 1957).

In the *muscular arteries*, especially those of the legs, it is possible to demonstrate primary foci of degeneration of the internal third of the media with secondary calcification in the form of plaques (*trachea-like arteries,* Monckeberg, 1903, 1904). In obliterating arteriosclerosis of the legs, the plaques of the intima, together with thrombosis, are important while calcification of the intima is less marked (Allen et al, 1955).

Arteriolosclerosis is characterized by the presence of hyalin, a proteic material, which

is deposited first in the internal then in the external layers of the arteriolar walls. Finally there is destruction of the wall structures, which become impregnated with lipoid material The narrowed lumen of the vessel usually has an eccentric position. A relationship between arteriolosclerosis and hypertension has been shown (Smith, 1955, 1956). The mechanism of formation of this deposit is unknown After the age of twenty the central arterioles of the spleen follicles have already been affected, while the small vessels of the trabeculae are spared In advanced age, the arterioles of kidney, pancreas, and myocardium (Wegelin, 1944; Linzbach, 1955) are affected The basal arteries of the brain show only mild changes while the middle cerebral artery and the small branches can be severely affected

Arteriolosclerosis is characterized by the presence of hyalin, a proteic material, which

is deposited first in the internal then in the external layers of the arteriolar walls. Finally there is destruction of the wall structures, which become impregnated with lipoid material The narrowed lumen of the vessel usually has an *eccentric* position. A relationship between arteriolosclerosis and hypertension has been shown (Smith, 1955, 1956). The mechanism of formation of this deposit is unknown After the age of twenty the central arterioles of the spleen follicles have already been affected, while the small vessels of the trabeculae are spared In advanced age, the arterioles of kidney, pancreas, and myocardium (Wegelin, 1944; Linzbach, 1955) are affected The basal arteries of the brain show only mild changes while the middle cerebral artery and the small branches can be severely affected.

PATHOGENESIS OF ARTERIOSCLEROSIS

During the last 100 years many hypotheses about the pathogenesis of human arteriosclerosis have been proposed, some of which became a "profession of faith"

Thrombus Theory. Rokitansky (1852) explained the thickenings of the intima of the aorta as thrombotic deposits This hypothesis was reasserted in modified form by Duguid (1948). The theory is based on the observation that arterial thrombi of the wall, sometimes in the form of flat deposits of fibrin, are promptly covered by the endothelium and are incorporated in the intima, hyalinized, and organized If the thickness is sufficient, the central areas can slough off and cause the precipitation of fatty material. If arteriosclerosis is already present, *secondary thrombi* are not rare and can have an influence on the ultimate growth of the plaques, especially in the coronary arteries Lubarsch (1905) showed arterial thrombi of the wall in 22 per cent of 425 cases of arteriosclerosis However, it is unlikely that the plaques of the intima are primarily formed by thrombosis The majority of the newly formed plaques of the intima are free of disintegration products of hemoglobin. In old plaques, the demonstration of fibrin and hemosiderin is not always evidence of thrombosis since they can also originate from ruptured, newly formed vasa vasorum (Muller, 1949, 1953) under the basal portion of the plaques. Fibrin can also penetrate the intima from the blood (Meyer, 1949)

Inflammation Theory. Virchow designated arteriosclerosis as *endarteritis chronica deformans.* It is clear that his conception of inflammation included the degenerative processes. This hypothesis of the inflammatory cause of arteriosclerosis has been subsequently resurrected and confirmed (Klinge, 1933; Bredt, 1941, Holle, 1943, Meyer, 1949). Two different mechanisms are thought to exist:

1. Primary, toxoinfectious, and inflammatory changes of the media (rheumatic fever, infections)

2. Changes in permeability of the endothelium due to infection with resulting penetration of plasma into the intima, especially in rheumatic fever and glomerulonephritis.

The advocates of this theory cannot answer several objections, and it is unlikely that inflammation can be accepted, in general, as the cause of arteriosclerosis.

Hemodynamic Theory. This concept is impaired by the difficulty of explaining why purely physical phenomena should cause an irregular increase in the thickness of arterial walls (Muller-Mohnssen, 1957). The theory of Thoma (1911, 1922, 1923) combines several theories He considers that the primary process of arteriosclerosis is a degeneration of the media followed by dilatation of the vessel and secondary, compensatory proliferation of the intima. Gradients of pressure in different directions in the intima would cause a focal proliferation of the intima.

The "Wear" Theory. This theory has played an important role in research without offering a definition for "wear" Aschoff (1925, 1939) believed that certain points of the arterial system were

terial walls It would be possible, with some limitations, to agree with this theory regarding the early changes in the lamina elastica interna, since these are of great importance in the biological balance of the arterial walls. There is no doubt that the internal elastic layers are submitted to severe changes in tension due to changing diameter.

Aging Theory. A real predisposition to arteriosclerosis due to senility was mathematically proved by Schinz et al. (1955). Burger (1939) advocated this theory and considered the increasing deposition of calcium, choleste-

rol, and mucopolysaccharides in the arterial wall, and the loss of water followed by decreased diffusion to be the causes. Daily experience casts doubt about the influence of the age factor on the development of arteriosclerosis As stated by Katz (1952), this theory is patently wrong.

Lipid Theory. This theory states that the content and type of fats in the plasma are the primary and essential causes for the formation of fibrous, fatty thickenings of the intima. The focal character of the changes presupposes additional factors causing localization in certain areas The fundamental experiments were performed at the beginning of this century by Ignatowski (1909), Chalatow (1912), and Anitschkow (1913, 1914, 1922, 1933), who produced arteriosclerosis in rabbits, chickens, and, under particular experimental conditions in other animals, through the use of a diet rich in cholesterol Fatty foci were produced in the thoracic aorta, bearing a striking similarity to the lipoid spots in the human aorta. If the diet is continued for a long time, the foci, containing proliferating cells that phagocyte fat (Duff et al., 1957), undergo degenerative changes and connective tissue proliferation (Scarff, 1927, Anitschkow, 1933) If mechanical, thermal, or chemical lesions are produced in the wall during the experiment, the lipid foci localize chiefly in the damaged areas. If, however, an experimental focal calcification of the media is produced first, through injection of epinephrine or vitamin D, the intimal foci form only at the points of calcification These experiments show that local lesions, causing a loosening and expansion of the arterial wall, favor the deposition of fatty materials in the intima. Conversely, changes which reduce the extensibility of the vascular wall, e.g , calcification of the media, hinder local deposition of fat in the intima This can be explained by the fact that calcification of the media guarantees a relatively high compression of the intima and increases its resistance In the same way, severe calcification of the media (Monckeberg type) is usually accompanied by relatively rare formation of plaques on the intima while arteriosclerosis obliterans of the femoral arteries is usually accompanied by rare calcification of the media Even though the connective tissue is able to synthesize cholesterol, it seems to be proved that the fatty material deposited in the intima comes from the blood. Several experiments lead to the belief that the high-molecular-weight lipoproteins can migrate into the intima through the endothelium in an unknown way (Evans et al , 1957; Goldberg et al., 1957). The experiments of Hueper (1941, 1956) have shown that other substances of high molecular weight (polyvinyl derivatives) can migrate from the blood into the intima. The most difficult and until now unsolved problem of the lipid theory is the question whether results of experiments on animals are valid when applied to human beings. The production of experimental arteriosclerosis requires relatively large amounts of cholesterol, equivalent to a daily supply of cholesterol about twenty times the normal values, if applied to man. Keys (1952), therefore, says: "From the animal experiments alone, the most reasonable conclusion would be that the cholesterol content of human diet is unimportant in human atherosclerosis." The atheromatosis caused by overload feeding differs from human atherosclerosis, apart from the heterogenous localization of the foci, because, not only are the arteries affected but lipoid deposits occur in the muscles, liver, spleen, kidneys, lungs, and eyes (Buck, 1954, Evans et al., 1957). Support for the utilization of the lipid hypothesis in human arteriosclerosis is given by the positive correlation of increased serum cholesterol content and atherosclerosis in diabetes, hypothyroidism, and idiopathic hypercholesterolemia However, it might be that entirely different factors play a role in these diseases. In diabetes, one should consider the importance of hypertension and acidosis; in hypothyroidism, that of disturbances of the metabolism and tissue respiration. Besides, it is necessary to keep in mind that long-lasting lipid nephrosis with high cholesterol values in the blood may occur without concomitant atherosclerosis. It is difficult to understand why human arteries usually are spared until the fourth decade of life in spite of the fact that human cholesterolemia is usually three times higher than that of rabbits (Duff et al, 1951) Biochemical studies on the composition of hematic fat, i e , increase of cholesterol/phospholipid ratio, decrease of alpha lipoproteins, and increase of beta lipoproteins (Bazz et al , 1951), demonstration of large molecules of the so-called S_f 10 to 20 lipoproteins

(Gofman et al., 1950, 1952) did not give clear-cut results in human beings One of the difficulties is due to the fact that it is impossible during life to evaluate with certainty the extent and severity of arteriosclerosis. At present, studies made during life to determine the *biochemical atherogenic index* failed to show any correlation with autopsy data (Paterson, 1954; Chapman et al, 1956) Comparative geographic and sociological studies can supply valuable data in regard to the importance of dietary factors in the causation of arteriosclerosis. However, they presuppose an exact quantitative and qualitative evaluation of arteriosclerosis on the autopsy material The work of Gore and Tejada (1957) reveals the trends which prevail in this field

Theory of Insufficient Nutrition of the Arterial Wall. This theory is based on the concept that both the (diffuse and the focal) processes of growth and the degenerative early changes lead to an irregular thickening of those sections of the arterial wall which are deprived of blood supply Since the thickness of the arterial walls increases steadily throughout life, the sections not receiving sufficient blood finally exceed the critical thickness This produces, at certain points, insufficient nutrition, followed by focal necrosis at the center of the thickened layers

In those arteries which present a predominant growth of the intima (aorta, coronary arteries) the foci of necrosis with deposition of fatty material and calcium salts are mainly situated in the deep layers of the plaques, near the media On the other hand, in those arteries which present a predominant growth of the media (femoral, renal) the centers of the degenerative processes are situated chiefly in the media, together with secondary fibrosis or dystrophic calcification It is not known whether the insufficient nutrition of the arterial wall is due to the fact that critical thickness is reached, resulting in deprivation of oxygen or nutrients (i.e., glucose), or to imperfect drainage of toxic metabolites. Actual measurements have proved that the critical thickness of the femoral artery is reached when the area of this vessel is about 12 mm² (Linzbach, 1944), that of the aorta when it attains a weight over 70 Gm (Meyer, 1951). The linear critical layer-thickness is estimated by Geiringer (1951) for the coronary arteries as 350 μ and for the aorta as 500 μ Considering the natural variations, it is possible to say that, below the critical layer-thickness, the arterial changes are essentially early ones while, above it the whole picture of arteriosclerotic foci with local tissue necrosis appears.

The local tissue necrosis that characterizes well-developed arteriosclerotic foci produces organizing processes which lead to secondary vascularization of the media and of the deep layers of the intima from the vasa vasorum (Linzbach, 1944, Geiringer, 1951; Drury, 1954). The organizing vessels evidently carry blood, because hemorrhages may occur in the depths of the intimal plaques. From this it appears that the compression in the deep layers of the intima must be lower than that in the newly formed vessels. This low compression can only be due to the fact that the internal connective layers of the arteriosclerotic plaques can absorb a large part of the wall tension The relationship between compression inside the plaques and that of neighboring spaces is significant in the further increase in the size of the focus. Not only is there a decrease of pressure in the intima, which favors an inflow of tissue fluids, but, through the presence of products of necrosis, the osmotic pressure of the foci can increase, thus attracting fluid from the surrounding tissues and the blood Whether the fatty substances present in the plaques result from tissue destruction, are synthetized, or originate from the blood and accumulate at the points of minimum pressure, is a still unsolved question In the last case, the lipid content of the blood would determine to a certain extent the fat content of the arteriosclerotic plaques, but would not be its cause. On the other hand, the uncommon and rapid fatty degeneration and the subsequent destruction of cells in a neglected tissue culture shows that tissue hypoxia may account for a large proportion of the visible fatty substances.

The hypothesis of faulty nutrition of the arterial wall explains the tendency toward arteriosclerosis of *muscular* men and hypertensive persons. Experiments have shown that the thickness of arterial walls increases more rapidly in men than in women, in athletes than in weaklings, and in hypertensive than in normotensive or hypotensive persons Therefore, the critical layer-thickness is reached

earlier in the former. Since the veins and the pulmonary artery are supplied with abundant vasa vasorum and are subjected to low compression, these vessels almost never reach the critical thickness. This is why sclerotic changes occur more seldom, or only to a small extent, in these vessels.

CONCLUSION

This review has discussed the unexplained pathogenesis of arteriosclerosis. The severe drop in pressure which occurs in the arterioles justifies the theory that the centrifuged stream of fluid in the intimal spaces of these vessels is relatively greater than it is in all the other vascular areas. This is particularly true when the flow from within to without the wall is opposed by high tonus of the muscular fiber, as in hypertension. In this particular case, there would be the condition for a "stasis" of fluids in the sense of Hueck (1920).

Considering the anatomical structure, the physical behavior of the pressure inside arterial walls, and their peculiar conditions of nutrition, a pathogenetic theory of arteriosclerosis has been developed. This permits the unification of the various earlier hypotheses

The new concept states that those sections of arterial wall which have no vessels and receive poor nourishment enlarge (1) due to a process of thickening, the speed of which depends upon age, constitution, sex, type of arteries, blood pressure, and local dynamic factors; and (2) because of all the known pathological early changes. These early changes produce a definite tendency to local changes

Growth and early changes cause the wall to reach a critical layer-thickness at a certain point; after this, local disturbances of nutrition arise and cause the development of arteriosclerotic foci with phenomena of destruction and organization.

In the arteries in which increases of the wall thickness occur, particularly in the intima (e g , aorta, coronary arteries), arteriosclerotic changes of the intima are most frequent, in those arteries in which the increase occurs particularly in the media (e.g , femoral and renal arteries), the changes occur chiefly in that tissue layer.

Gross and microscopic changes caused by atherosclerosis and arteriosclerosis

CHARLES BRUCE TAYLOR

The term *arteriosclerosis* is usually employed as a general term covering many of the arteriopathies However, it is only a descriptive term meaning "hardening of the arteries" and wisely has been excluded from the classification of arteriopathies by the Committee on Nomenclature of The American Society for the Study of Arteriosclerosis (Wolffe et al). Since arteriosclerosis only implies that an artery is hard, due to scarring and calcification, and does not indicate pathogenesis, this term might best be relegated for use as a descriptive adjective for end-stage changes in arteries due to a variety of causes The afore-mentioned classification by the Committee on Nomenclature will be followed in this section. *Atherosclerosis* will be considered extensively, other arteriopathies will either be discussed only briefly or merely defined

Classification of Arteriopathies Based on Report of Committee on Nomenclature of American Society for Study of Arteriosclerosis

- I Degenerative arteriopathies
  - A. Atherosclerosis
  - B. Medial calcific sclerosis (Monckeberg's)
  - C Arterionecrosis
- II Productive or hyperplastic arteriopathy (hypertensive vascular disease)
- III. Inflammatory arteriopathies
  - A Infectious
    - 1 Bacterial
    - 2. Plasmodial
    - 3. Viral
  - B Attributable to abnormal tissue responses (hypersensitivity)
    - 1. Polyarteritis nodosa (periarteritis nodosa, essential panarteritis)
    - 2 Arteritis associated with systemic lupus erythematosus
    - 3 Arteritis associated with scleroderma and acrosclerosis
    - 4. Arteritis associated with rheumatic fever
    - 5 Thromboangiitis obliterans
    - 6 Cranial arteritis (giant-cell arteritis; temporal arteritis)
  - C. Traumatic arteritis
    - 1. Chemical arteritis
    - 2 Physical arteritis
    - 3 Mechanical arteritis
  - D. Arteriopathies of undetermined or uncertain origin
    - 1. Thrombotic thrombocytopenic purpura
    - 2. Nodular vasculitis
    - 3. Aortic arch arteritis
- IV. Primary thromboembolic arteriopathies
  - A. Embolism
    - 1. Detached thrombus or vegetation

Fig. 15-4. A. *Early atherosclerotic lesion showing fat-laden macrophages lying in subendothelium and within the confines of the internal elastic lamina. The macrophages are intermingled with fibrocytes which also appear to have proliferated as a response to the increased concentration of lipids in the subendothelial zone B Severe coronary atherosclerosis with intramural hemorrhage and thrombosis The media consists of the darker, more cellular, thin rim of tissue lying just inside the loose-textured adventitia The intima has thickened to three to five times the thickness of the media and consists of grumous plaques lying deep in the thickened intima (lower left), new groups of fat-laden macrophages lying just to the right of the thrombus in the lumen, and dense hyaline scars containing only a few cells and frequent cholesterol clefts Two vasa vasorum are present on the left at the junction of the media with the thickened intima. The dark crescent-shaped area in the thickened intima which lies toward the bottom and the left is a large intramural hemorrhage resulting from rupture of vasa vasorum which had proliferated into a partially degenerated atheromatous deposit. The dark blood clot in the lumen is attached at the site of maximal disruption and inflammation of the endothelium which was caused by the reaction to the intramural hemorrhage In some instances intramural hemorrhage alone may occlude the lumens of coronary arteries, the space occupied by the hemorrhage into the wall being sufficient to completely occlude the lumen.*

2. Air
3. Fat
4. Foreign bodies

B. Essential arteriothrombosis (in situ)

V. Combined forms of arteriopathies

Combination of any of the afore-mentioned arteriopathies. The combination of atherosclerosis and medial calcific sclerosis or arterionecrosis is frequent, and suggests that medial lesions may often determine the localization of atheromas in susceptible individuals

DEGENERATIVE ARTERIOPATHIES

Atherosclerosis. Atherosclerosis has been described as the keystone in the arch of cardiovascular disease and is unquestionably the most important single disease afflicting man today (Katz and Dauber, 1945). Fortunately, the "senescence theory" of the pathogenesis of atherosclerosis is rapidly being replaced by a concerted research effort by scientists who have refused to believe that atherosclerosis is the inevitable result of the physiological aging process. During the past several decades, particularly during the years since World War II, many aspects of this disease have been clarified and it is highly probable that within the next few decades atherosclerosis will become a disease of minor importance.

Atherosclerosis is characterized by intimal deposits of lipids with variable degrees of scarring, hemorrhage, and calcification (Fig 15-4). The genesis of this disease process can be presented better after a brief consideration of the *anatomy and physiology* of arterial tissue Arterial walls have three layers: intima, media, and adventitia. The *intima*, in young, healthy arteries, consists of a layer of endothelial cells and a very thin subendothelial layer. In the thin subendothelial layer there are a few primitive mesenchymal cells with multipotent regenerative powers which play a major role in the repair of vascular tissue and in the genesis of atherosclerosis The *media*, in most arteries, is delineated by an internal and an external

elastic membrane and is composed of variable numbers of additional well-oriented elastic membranes, collagen, and smooth muscle cells lying in a ground substance. The *adventitia* consists of loose connective tissue with its collagenous and elastic fibers running predominantly parallel to the longitudinal axis. *Muscular arteries* have only internal and external elastic membranes, cerebral arteries have only *a thick* internal elastic membrane. Nutrition is supplied to the adventitia and much of the media by *vasa vasorum*. However, the intima and inner media depend upon diffusion from luminal blood for nutrition. This diffusion of luminal plasma into and out of the intima and superficial media appears important in the genesis of atherosclerosis. Indeed, there is considerable clinical and experimental evidence which indicates that plasma lipids precipitate out in the subendothelial spaces of the intima during diffusion to and from the intima and superficial media. Recent studies on monkeys indicate *a critical level* of total serum cholesterol of about 250 mg/100 ml, when levels are 250 mg/100 ml or higher, lipids precipitate in the subendothelium and are phagocytized by the multipotent mesenchymal cells in the subendothelium (Taylor et al., 1957). Phagocytosis of lipids in the subendothelium represents an early form of atherosclerosis (Fig. 15-4A). The propensity of lipids to accumulate within the intima is striking and it would appear that the internal elastic membrane usually *delimits early* deposits of lipids and atheromas in the walls of arteries. Flow of interstitial fluids in the media via vasa vasorum must be accomplished under much more stable conditions because lipids do not precipitate out in this layer unless the structure of the media has been markedly altered. Leary proposed that the presence of lipids in the intima also stimulates proliferation and differentiation of multipotent mesenchymal cells into fibrocytes, resulting in a mixed intimal lesion composed of lipophages and connective tissue (Fig. 15-4). Fibrous elastic scars become quite thick and often form a white pearly *scar over* a foam-cell atheroma; the atheroma later degenerates and leaves a yellow grumous mass of lipids deep *in the thickened* intima (Fig. 15-4B). With the increased thickness of the intima, this portion of the vessel now becomes vascularized with vasa vasorum originating in

Fig. 15-5. Large aneurysms of lower abdominal aorta and left common iliac artery. The site of rupture of the aortic aneurysm lies in the anterior midline in the upper half of the aneurysm. There is marked *ectasia* of the right common iliac and the lesser iliac arteries

the media and from the endothelial surface. These vasa vasorum lie in the poorly formed, often degenerating atherosclerotic plaques and frequently *rupture* with *subsequent hemorrhage* into the plaque (Paterson, 1955). These hemorrhages result in enlargement of atheromas, *greater narrowing* of lumens of vessels and, *all too frequently*, in *occlusion, thrombosis, or both* (Fig. 15-4B). Other late changes consist of severe medial degenerative changes with calcification beneath the atheromas, this *may lead to the development* of aneurysmal *dilatation* and *rupture* (Fig. 15-5). Also, the intimal scars over atheromas may *ulcerate* and lead to *thrombosis*.

Atherosclerosis *may* develop secondary to arteriopathies from other causes (Fig. 15-6) (Waters and Taylor). The unique response of arterial tissue to injury associated with various *arteriopathies* will be reviewed and its

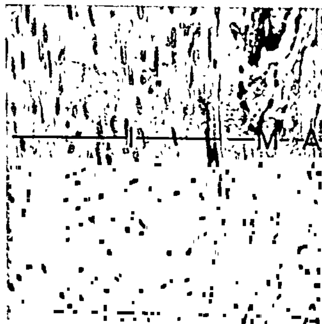

Fig. 15-6. The profound effect of hypercholesterolemia on vascular repair at sites of injury and degeneration is demonstrated *Upper:* Cross section of a healed arterial lesion produced by freezing the aorta of a normocholesterolemic rabbit ingesting a low-fat, cholesterol-free diet. The adventitia (*A*) is composed of dense bundles of collagen The damaged, degenerated media (*M*) has few viable cells and is partially calcified. There is essentially no reparative response in the media. Within the intima (*I*) multipotent mesenchymal cells have proliferated, differentiated, and formed an essentially new arterial wall which lies within the degenerated shell of the old injured media (*M*). *Lower.* Cross section of the inadequate healing process occurring at a site of injury produced by freezing the aorta of a hypercholesterolemic rabbit (average serum cholesterol level, 1,090 mg/100 ml). The adventitia (*A*), degenerated media (*M*), and proliferated intima (*I*) are indicated. Comparison with section above demonstrates the marked alteration in the intimal repair. Lipophages occupy the inner one-half of the proliferated intima The upper half of the intimal scar shows only a few scattered fibroblasts lying in partially hyalinized scar tissue which in some areas shows "mucinous" degeneration.

role in the development of atherosclerosis will be outlined Almost all of the regenerative and reparative capacity of arterial tissue stems from the subendothelial primitive mesenchymal cells mentioned earlier. In the experimental animal, these multipotential cells have the ability to form an essentially new vascular wall in the framework of a proliferated intima (Taylor, 1955). There is very little regeneration of vascular tissue in an injured media In hypercholesterolemic animals and apparently in man, intimal proliferation following medial degeneration consists of a mixed response, with some primitive mesenchymal cells being diverted to phagocytosis of subendothelial lipids, and the more desirable response of regeneration of new functional vascular tissue is adversely affected (Fig. 15-6). Thus, it appears that, *in the moderately hypercholesterolemic man, arteriopathies due to other causes enhance the rate of development of atherosclerosis and jeopardize the vascular repair process* Intimal scars should contain well-oriented new elastic membranes, fibrocytes, smooth muscle cells, and a modest number of well-oriented collagen bundles. In man and in hypercholesterolemic animals, intimal scars are composed of an abundance of fat-laden macrophages, poorly formed, often hyalinized collagen with very meager amounts of poorly oriented elastic tissue; no smooth muscle cells, and a few scattered fibrocytes (Fig. 15-6). With partial loss of elastic and contractile characteristics, the arterial bed is left with a decreased quantity of functional tissue available to dilate and contract with each cardiac cycle. Consequently the potential for development of new arterial lesions, with subsequent development of more atherosclerosis and poor intimal scars, is further enhanced. This vicious cycle of events explains, in part, why atherosclerosis usually develops more rapidly during the later decades of life.

As mentioned previously, atherosclerosis is initially confined to the intima. However, if disruptions occur in the internal elastic membrane, *many lipid-laden macrophages are found in the media.* A common place for such a change is in larger cerebral arteries at the base of the brain where the so-called "collar-button" atheromatous lesion is found, a large intimal atheroma becomes constricted as it passes through a defect in the internal elastic membrane then enlarges again in the media

The distribution of atherosclerosis is interesting The disease is uncommon in the lesser pulmonary circulation unless pulmonary arterial hypertension is present. In the systemic circulation, the disease affects the aorta and many of its primary and secondary branches, hypertension hastens the genesis of atherosclerosis in these vessels. Almost all large and moderate-sized arteries of the systemic arterial

tree lying in loose-textured tissue may be sites of atherosclerosis However, when these vessels enter firm parenchymatous organs or tissues, atherosclerosis no longer is present. A striking example of this is the severe atherosclerosis which is present in epicardial coronary arteries and renal arteries before they enter the myocardium or renal parenchyma Immediately after entrance into their respective organs, atherosclerosis ceases. Arteries within firm parenchymatous tissue may show marked intimal scarring but almost never show atheromatosis.

Prevention of Atherosclerosis. There is a good deal of clinical and experimental evidence which indicates that atherosclerosis is a disease that could be largely eradicated by preventive medical measures. There is indirect evidence in studies of population groups by Keys and Anderson (1955), substantiated by studies of monkeys (Taylor et al, 1957), which indicates that atherosclerosis develops only when serum cholesterol levels are above 250 mg/100 ml, conversely, if levels are below about 200 mg/100 ml, atherosclerosis will not develop even in the presence of arterial injury Fortunately, the medical profession and populations in overfed nations are slowly but surely adopting the philosophy that cholesterol and other fats should be reduced to about 20 to 30 per cent of the current average rate of consumption With reduced levels of total serum cholesterol, the precipitation and accumulation of lipids in the intima of arteries should be reduced to such an extent as to markedly inhibit the development of atherosclerosis and thus make it a disease of minor importance

Reversibility of Atherosclerosis. The reversibility of atherosclerosis deserves careful consideration because of the prevailing concept that atherosclerosis is not reversible. Reversibility of the disease was demonstrated in experimental animals many years ago (Anitschkow, 1933) Evidence for reversibility of the disease in human beings is necessarily indirect but most pathologists feel the disease undergoes regressive changes in relatively short periods in patients with terminal carcinoma, tuberculosis, and other wasting diseases There is a modest amount of material in the literature comparing atherosclerosis in wasting diseases with the affection in patients dying suddenly (Wilens, 1947) It is important to keep in mind that atherosclerosis consists of foreign material (lipids) lying in cells and interstitial spaces in arterial tissue and that, under proper conditions, these lipids can be removed from the tissue. Proper conditions would appear to be *a reduction in the total concentration of certain plasma lipids* (with the total serum cholesterol serving as an index of their concentration), so that lipids can be mobilized and removed from the arterial wall. As originally shown by Anitschkow in experimental animals, reversal of the disease requires relatively long periods of time; in the experimental animal, florid atherosclerotic lesions are almost completely replaced by an intimal scar within periods of 18 to 24 *months*.

MEDIAL CALCIFIC SCLEROSIS (MÖNCKEBERG'S)

Monckeberg's medial calcific sclerosis is a disease of uncertain etiology which is characterized by medial calcification and fibrosis The intima may show only fibrosis or may show concomitant atherosclerosis. Muscular arteries, such as the femoral, tibial, and radial, are affected It is a disease of adult life which tends to progress with aging. Femoral arteries show segmental calcification in circumferential rings resembling cartilaginous rings in the trachea. Smaller arteries such as the radials show extensive pipestem medial calcification. Hueper, 1944, has attributed the disease to calcification following a degenerative change due to toxic vasotonic agents of either exogenous or endogenous origin and cites a number of known exogenous agents that have resulted in medial calcification experimentally, these toxic agents include epinephrine, vitamin D, and nicotine.

ARTERIONECROSIS

Cystic Medionecrosis. Erdheim (1930) described the formation of mucoid cysts in areas of dissolution of elastic tissue and smooth muscle cells and called the condition "medionecrosis aortae idiopathica cystica" It has been shortened to *cystic medionecrosis* and is generally accepted as the predisposing lesion in the majority of dissecting aneurysms of the aorta Hypertension is a common predisposing clinical condition. It has been suggested that the degenerative medial lesions may be either secondary to obliterative changes in the vasa

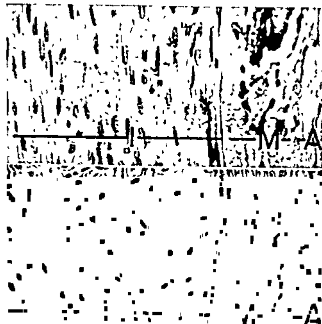

Fig. 15-6. The profound effect of hypercholesterolemia on vascular repair at sites of injury and degeneration is demonstrated. *Upper:* Cross section of a healed arterial lesion produced by freezing the aorta of a normocholesterolemic rabbit ingesting a low-fat, cholesterol-free diet. The adventitia (A) is composed of dense bundles of collagen. The damaged, degenerated media (M) has few viable cells and is partially calcified. There is essentially no reparative response in the media. Within the intima (I) multipotent mesenchymal cells have proliferated, differentiated, and formed an essentially new arterial wall which lies within the degenerated shell of the old injured media (M). *Lower:* Cross section of the inadequate healing process occurring at a site of injury produced by freezing the aorta of a hypercholesterolemic rabbit (average serum cholesterol level, 1,090 mg/100 ml). The adventitia (A), degenerated media (M), and proliferated intima (I) are indicated. Comparison with section above demonstrates the marked alteration in the intimal repair Lipophages occupy the inner one-half of the proliferated intima. The upper half of the intimal scar shows only a few scattered fibroblasts lying in partially hyalinized scar tissue which in some areas shows "mucinous" degeneration.

role in the development of atherosclerosis will be outlined Almost all of the regenerative and reparative capacity of arterial tissue stems from the subendothelial primitive mesenchymal cells mentioned earlier. In the experimental animal, these multipotential cells have the ability to form an essentially new vascular wall in the framework of a proliferated intima (Taylor, 1955). There is very little regeneration of vascular tissue in an injured media. In hypercholesterolemic animals and apparently in man, intimal proliferation following medial degeneration consists of a mixed response, with some primitive mesenchymal cells being diverted to phagocytosis of subendothelial lipids, and the more desirable response of regeneration of new functional vascular tissue is adversely affected (Fig. 15-6). Thus, it appears that, *in the moderately hypercholesterolemic man, arteriopathies due to other causes enhance the rate of development of atherosclerosis and jeopardize the vascular repair process* Intimal scars should contain well-oriented new elastic membranes, fibrocytes, smooth muscle cells, and a modest number of well-oriented collagen bundles. In man and in hypercholesterolemic animals, intimal scars are composed of an abundance of fat-laden macrophages, poorly formed, often hyalinized collagen with very meager amounts of poorly oriented elastic tissue, no smooth muscle cells, and a few scattered fibrocytes (Fig 15-6). With partial loss of elastic and contractile characteristics, the arterial bed is left with a decreased quantity of functional tissue available to dilate and contract with each cardiac cycle. Consequently the potential for development of new arterial lesions, with subsequent development of more atherosclerosis and poor intimal scars, is further enhanced This vicious cycle of events explains, in part, why atherosclerosis usually develops more rapidly during the later decades of life.

As mentioned previously, atherosclerosis is initially confined to the intima. However, if disruptions occur in the internal elastic membrane, *many lipid-laden macrophages are found in the media.* A common place for such a change is in larger cerebral arteries at the base of the brain where the so-called "collar-button" atheromatous lesion is found, a large intimal atheroma becomes constricted as it passes through a defect in the internal elastic membrane then enlarges again in the media.

The distribution of atherosclerosis is interesting The disease is uncommon in the lesser pulmonary circulation unless pulmonary arterial hypertension is present In the systemic circulation, the disease affects the aorta and many of its primary and secondary branches, hypertension hastens the genesis of atherosclerosis in these vessels. Almost all large and moderate-sized arteries of the systemic arterial

grees of arterial necrosis and inflammation and usually an associated thrombosis proximal and distal to the embolic occlusion

Essential Arteriothrombosis (in situ). In conditions associated with hypercoagulability of blood, such as *polycythemia vera*, thrombosis occurs in smaller arteries without apparent local vascular changes which would account for the thrombosis

COMBINED FORMS OF ARTERIOPATHIES

Any of the afore-mentioned arteriopathies may be superimposed one upon the other As discussed above, atherosclerosis frequently develops at sites of repair of arterial tissue, regardless of the pathogenesis of the injury or degeneration. Since atherosclerosis is such an important disease, the fact that its rate of development in man is increased by the presence of other arteriopathies deserves reiteration. However, it is much more important that the preventability of atherosclerosis in both normal arterial tissue and the loci of other arteriopathies be stressed Recent observations on monkeys (Taylor et al, 1957) demonstrate a critical range (about 250 mg/100 ml) of serum cholesterol above which lipids accumulate in arterial tissue When levels of serum cholesterol are below 200 mg/100 ml, lipids do not accumulate in either normal arterial tissue or at sites of artificially produced arteriopathy. Work by earlier workers reviewed by Keys and Anderson (1955), and their more recent studies, although of necessity not as clear-cut as the studies on monkeys, indicate a very similar picture in man.

VASCULAR DISEASE IN DIABETES

This special form of degenerative vascular disease was not included in the classification of arteriopathies which was followed in this section. However, the author feels that vascular disease in diabetes mellitus is an important and separate disease entity and should be mentioned at least briefly. A more complete discussion is available in a publication by Warren and LeCompte (1952). In diabetes mellitus, medial degenerative changes are conspicuous in small arteries, arterioles, venules, and capillaries. It has been suggested by Dry and Hines (1941) that diabetes mellitus is an inherent weakness affecting both carbohydrate metabolism and certain poorly understood factors concerned in the maintenance of normal, healthy arterial walls They further suggest that medial degenerative changes in vasa vasorum may result in medial degeneration of larger arteries just as medial degeneration of vasa nervorum and retinal arterioles result in diabetic neuropathies and diabetic retinitis, respectively. Thus, many of the late arterial lesions of diabetes mellitus would be examples of combined arteriopathies: degenerative changes, primarily medial, associated with diabetes mellitus with superimposed atherosclerosis overlying sites of medial degeneration.

vasorum or to the direct effects of hypertension on medial structures. However, the cause of this disease is uncertain.

Toxic Arterionecrosis. This lesion is characterized by necrosis and degeneration in various parts of all coats of the arteries and is ascribed to either exogenous (e.g., diphtheria) or endogenous (e g., renal, adrenal) toxins.

Arterionecrosis of Physical Origin. This is necrosis of arterial tissue due to physical agents such as gross mechanical or thermal trauma.

Arteriolar Necrosis (Arteriolonecrosis). The pathological anatomy of this lesion consists of intramural fibrinoid necrosis with variable degrees of deposition of perivascular fibrinoid, focal hemorrhagic and intravascular thrombosis. The most severe changes are seen in the renal afferent arterioles and less frequently in the renal intralobular arteries and other arterioles. These lesions are characteristic of so-called "malignant" or "accelerated" hypertension and are superimposed on hyperplastic arteriopathy.

PRODUCTIVE OR HYPERPLASTIC ARTERIOPATHY (HYPERTENSIVE VASCULAR DISEASE)

Protracted increased pressures in the systemic or pulmonary arterial system result in hyperplastic changes, primarily in small arteries and arterioles Arteries develop muscular hyperplasia and intimal thickening with formation of new elastic lamina, later, medial fibrosis develops Arterioles show muscular hyperplasia with subsequent hyaline medial degeneration.

INFLAMMATORY ARTERIOPATHIES

Infectious. SYPHILITIC ARTERIOPATHY This is due to the *Treponema pallidum* The adventitia and vasa vasorum are primarily affected, other changes are secondary

BACTERIAL. Local invasion of bacteria, particularly pathogenic *cocci*, causes this arteriopathy which can develop into a so-called mycotic aneurysm.

PLASMODIAL. This is a disease of small arteries associated with the agglutination of erythrocytes in malaria.

VIRAL Rickettsial as well as viral infections affecting small arteries are included in this category.

Attributable to Abnormal Tissue Responses (Hypersensitivity). This group of arteriopathies has been listed above and will be only briefly mentioned here. The cause of each disease is not clearly established but, in many instances, a hypersensitive reaction is strongly implicated.

Traumatic Arteritis. CHEMICAL. Chemical agents including drugs may injure vessels by local contact at sites of injection or be indirectly injurious following absorption

PHYSICAL. Physical agents that may cause arterial injury and arteritis include light, heat, cold, x-rays, and radioactive substances.

MECHANICAL. Mechanical forces may injure arterial tissue by direct impact or indirectly by applying abnormal forces to the body generally; e.g., rapid deceleration in an automobile accident may result in an injury to or tear of the aortic arch (Tannenbaum and Ferguson, 1948).

Undetermined or Uncertain Origin. In this category are arteriopathies of most uncertain origin. In certain other arteriopathies categorized earlier, the pathogenesis was not clearly established but etiologic factors were felt to be sufficiently established to warrant their classification elsewhere.

THROMBOTIC THROMBOCYTOPENIC PURPURA This disease is relatively uncommon and, according to Meacham et al. (1951), has its primary lesion in arterioles and capillaries Focal intimal lesions develop, followed by platelet thrombi and a secondary thrombocytopenia with purpura.

NODULAR VASCULITIS. This disease is one of several affecting subcutaneous adipose tissue and its vessels. This group of diseases has been described by Allen (1957).

AORTIC ARCH ARTERITIS This disease has been variously labeled as *pulseless disease*, young female arteritis, and aortic arch arteritis It is a proliferative arteritis involving the aortic arch and its major branches Ross and McKusick (1953) have reviewed 100 cases of this syndrome

PRIMARY THROMBOEMBOLIC ARTERIOPATHIES

Embolism. Arterial reactions associated with lodgement of emboli from thrombi, vegetations, and such foreign substances as air, fat, and other materials, consist of variable de-

grees of arterial necrosis and inflammation and usually an associated thrombosis proximal and distal to the embolic occlusion.

Essential Arteriothrombosis (in situ). In conditions associated with hypercoagulability of blood, such as *polycythemia vera*, thrombosis occurs in smaller arteries without apparent local vascular changes which would account for the thrombosis.

COMBINED FORMS OF ARTERIOPATHIES

Any of the afore-mentioned arteriopathies may be superimposed one upon the other. As discussed above, atherosclerosis frequently develops at sites of repair of arterial tissue, regardless of the pathogenesis of the injury or degeneration. Since atherosclerosis is such an important disease, the fact that its rate of development in man is increased by the presence of other arteriopathies deserves reiteration. However, it is much more important that the preventability of atherosclerosis in both normal arterial tissue and the loci of other arteriopathies be stressed. Recent observations on monkeys (Taylor et al., 1957) demonstrate a critical range (about 250 mg/100 ml) of serum cholesterol above which lipids accumulate in arterial tissue. When levels of serum cholesterol are below 200 mg/100 ml, lipids do not accumulate in either normal arterial tissue or at sites of artificially produced arteriopathy. Work by earlier workers reviewed by Keys and Anderson (1955), and their more recent studies, although of necessity not as clear-cut as the studies on monkeys, indicate a very similar picture in man.

VASCULAR DISEASE IN DIABETES

This special form of degenerative vascular disease was not included in the classification of arteriopathies which was followed in this section. However, the author feels that vascular disease in diabetes mellitus is an important and separate disease entity and should be mentioned at least briefly. A more complete discussion is available in a publication by Warren and LeCompte (1952). In diabetes mellitus, medial degenerative changes are conspicuous in small arteries, arterioles, venules, and capillaries. It has been suggested by Dry and Hines (1941) that diabetes mellitus is an *inherent weakness* affecting both carbohydrate metabolism and certain poorly understood factors concerned in the maintenance of normal, healthy arterial walls. They further suggest that medial degenerative changes in vasa vasorum may result in medial degeneration of larger arteries just as medial degeneration of vasa nervorum and retinal arterioles result in diabetic neuropathies and diabetic retinitis, respectively. Thus, many of the late arterial lesions of diabetes mellitus would be examples of combined arteriopathies: degenerative changes, primarily medial, associated with diabetes mellitus with superimposed atherosclerosis overlying sites of medial degeneration.

vasorum or to the direct effects of hypertension on medial structures. However, the cause of this disease is uncertain.

Toxic Arterionecrosis. This lesion is characterized by necrosis and degeneration in various parts of all coats of the arteries and is ascribed to either exogenous (e.g., diphtheria) or endogenous (e.g., renal, adrenal) toxins.

Arterionecrosis of Physical Origin. This is necrosis of arterial tissue due to physical agents such as gross mechanical or thermal trauma.

Arteriolar Necrosis (Arteriolonecrosis). The pathological anatomy of this lesion consists of intramural fibrinoid necrosis with variable degrees of deposition of perivascular fibrinoid, focal hemorrhagic and intravascular thrombosis The most severe changes are seen in the renal afferent arterioles and less frequently in the renal intralobular arteries and other arterioles These lesions are characteristic of so-called "malignant" or "accelerated" hypertension and are superimposed on hyperplastic arteriopathy.

PRODUCTIVE OR HYPERPLASTIC ARTERIOPATHY (HYPERTENSIVE VASCULAR DISEASE)

Protracted increased pressures in the systemic or pulmonary arterial system result in hyperplastic changes, primarily in small arteries and arterioles Arteries develop muscular hyperplasia and intimal thickening with formation of new elastic lamina, later, medial fibrosis develops Arterioles show muscular hyperplasia with subsequent hyaline medial degeneration.

INFLAMMATORY ARTERIOPATHIES

Infectious. SYPHILITIC ARTERIOPATHY This is due to the *Treponema pallidum* The adventitia and vasa vasorum are primarily affected, other changes are secondary

BACTERIAL. Local invasion of bacteria, particularly pathogenic *cocci*, causes this arteriopathy which can develop into a so-called mycotic aneurysm.

Attributable to Abnormal Tissue Responses (Hypersensitivity). This group of arteriopathies has been listed above and will be only briefly mentioned here. The cause of each disease is not clearly established but, in many instances, a hypersensitive reaction is strongly implicated.

Traumatic Arteritis. CHEMICAL Chemical agents including drugs may injure vessels by local contact at sites of injection or be indirectly injurious following absorption.

PHYSICAL. Physical agents that may cause arterial injury and arteritis include light, heat, cold, x-rays, and radioactive substances

MECHANICAL. Mechanical forces may injure arterial tissue by direct impact or indirectly by applying abnormal forces to the body generally; e.g., rapid deceleration in an automobile accident may result in an injury to or tear of the aortic arch (Tannenbaum and Ferguson, 1948).

Undetermined or Uncertain Origin. In this category are arteriopathies of most uncertain origin. In certain other arteriopathies categorized earlier, the pathogenesis was not clearly established but etiologic factors were felt to be sufficiently established to warrant their classification elsewhere.

THROMBOTIC THROMBOCYTOPENIC PURPURA This disease is relatively uncommon and, according to Meacham et al (1951), has its primary lesion in arterioles and capillaries. Focal intimal lesions develop, followed by platelet thrombi and a secondary thrombocytopenia with purpura.

NODULAR VASCULITIS. This disease is one of several affecting subcutaneous adipose tissue and its vessels. This group of diseases has been described by Allen (1957).

AORTIC ARCH ARTERITIS This disease has been variously labeled as *pulseless disease*, young female arteritis, and aortic arch arteritis It is a proliferative arteritis involving the aortic arch and its major branches Ross and McKusick (1953) have reviewed 100 cases of this syndrome

PRIMARY THROMBOEMBOLIC ARTERIOPATHIES

Embolism. Arterial reactions associated with lodgement of emboli from thrombi, vegetations, and such foreign substances as air, fat, and other materials, consist of variable de-

of the smooth fibers of the media and hyaliniza-
tion and proliferation of the subintima; these [illegible]

[illegible]

head et al, [illegible]). [illegible] either by the injection of sulfonamides or by surgery, a peculiar type of medial calcification follows, this has been attributed to the development of hyperparathyroidism secondary to the kidney insufficiency. All these experiments point to the fact that a normally functioning kidney is necessary for the maintenance of the integrity of the medial layer of the arteries

Dietary Factors. The influence of diet in the maintenance of normal arteries has been demonstrated mainly under the following circumstances.

CHOLINE DEFICIENCY. This deficiency in rats produces medial sclerosis of the aorta and the coronary arteries which is aggravated by cholesterol feeding

LATHYRISM Rats and turkeys fed with seeds of *Lathyrus odorata* develop dissecting aneurysms of the aorta and bone lesions.

VITAMIN E DEFICIENCY. This deficiency in guinea pigs, but not in rats, produces medial degeneration and calcification of the aorta

ENDOCRINE GLANDS Rats with diabetes caused either by alloxan administration or by subtotal pancreatectomy show arteriolar hyalinization, it is possible that these changes are dependent not on the pancreas but on a secondary kidney damage.

OTHER FACTORS The intravenous injection of al- [illegible] necrosis of the [illegible] infiltration is observed and a lesion similar to human atherosclerosis may result

From the above results it appears that, although an injury to the arterial media can be produced in many ways, the histological picture may show a great uniformity, namely, an acute inflammatory response and a repair process Different noxious stimuli evoke a similar picture, which is apparently due to a constant pathological response of the arterial media Consequently, it cannot always be concluded that the experimental lesions are caused by mechanisms similar to those of their clinical counterparts.

RESULTS OF EXPERIMENTAL ATHEROSCLEROSIS

Degenerative changes, mainly limited to the intima, are characteristic of atherosclerosis, extension of the changes into the media, however, are so common that many authors suggest that atherosclerosis may really start in the latter. Furthermore, although the process may seem to be primarily of a degenerative nature, the role of inflammation has not been completely ruled out in some instances (Saphir and Gore). For brevity's sake, it will be assumed that (1) the arterial changes of atherosclerosis develop primarily *in the intima*, and (2) inflammation is *not* a primary phenomenon in the majority of the atherosclerotic lesions.

It will be useful to review the various methods of production of atherosclerosis in different species

Rabbit. The rabbit is the first animal in which atherosclerotic lesions have been consistently produced, the fact that the lesions were first obtained by feeding cholesterol has greatly influenced later research. Cholesterol is a foreign substance to herbivora which, after weaning, do not normally ingest this solid alcohol. When cholesterol is given in amounts varying from 250 to 1,000 mg per day for 2 or 3 months, a marked hyperlipemia and hypercholesterolemia is produced, and gross atherosclerotic lesions appear in 70 to 80 per cent of the animals, at the same time, xanthomatous deposits in the pulmonary circulation, cartilages, cornea, and liver, as well as amyloidosis of the skin, ectopic blood formation, and other signs of damage can also be found. The fact that 20 to 30 per cent of the cholesterol-fed rabbits are naturally resistant to this form of atherosclerosis must be remembered when experiments consisting of a few animals are statistically analyzed. The way in which cholesterol is given does not influence the severity of the lesions although the iodide number of the accompanying oil does influence the amount of the change. The early lesions induced by this method consist of sudanophilic droplets located in the subendothelial ground substance of the intima and may appear even before the occurrence of pronounced changes in the plasma level of lipids, alternative explanations suggest that cholesterol is first phagocyted by the endothelial lining cells and then released into the ground substance. However, the subsequent gross hypercholesterolemia undoubtedly influences the deposition of cholesterol in the intima and the subsequent arterial reactions. As a whole, it seems well established that feeding cholesterol to rabbits induces local changes in the intima and in the media (increased endothelial permeability, increased subintimal mucopolysaccharides, appearance of a phagocyting capacity of the endothelial cells) and that subsequently the cholesterol-loaded plasma, by a process of ultrafiltration, is able to cause local deposits, proliferation of foam cells, fibroblasts, and other damage. Older theories trac-

Experimental arteriosclerosis and atherosclerosis

M. MALINOW

Degenerative changes of the arterial walls have been produced by different methods and in many species. Thus, several questions arise in connection with the significance of these findings:

1. Are the degenerative lesions of different species of animals equivalent?
2. What mechanisms are involved in producing these lesions?
3. Is it possible to influence, therapeutically or otherwise, the induced lesions?
4. Can the results of animal experiments be applied to man?

For the last one-half century, myriads of experiments have been performed in trying to answer these questions and, although some points have been clarified, others still need further research

All arterial degenerative changes can be grouped under the name of *arteriosclerosis*, while the term *atherosclerosis* refers only to lipid infiltration and cellular proliferation, mainly centered in the intima. The pathological changes are probably equivalent in different species of animals when the histological picture is similar, this also applies to man Naturally, there are reservations in regard to the extension to human beings of experimental results obtained in animals Furthermore, it is recognized that, although lesions may be morphologically identical, the mechanisms involved in their production may not be identical in different species.

The "degenerative" lesions are not sharply delimited, but it is customary to separate from them certain pathological processes, such as acute necrotizing arteritis, the fibrinoid changes seen in the "collagen diseases," and others. Consequently, these arterial lesions will not be considered. Although the pathological picture (and the pathogenic mechanisms?) of the degenerative lesions in the systemic and in the pulmonary circulations may be similar, this discussion shall be limited to the systemic circulation Many of the conclusions that will be reached for the systemic arteries can possibly be extended to the lesser circulation.

METHODS USED FOR CAUSING EXPERIMENTAL ARTERIOSCLEROSIS

Different methods can be used to cause an injury to the arterial media, a subsequent acute inflammatory response, and an associated process of repair similar to those of human arteriosclerosis.

Direct Trauma. Vascular scars have been produced in rabbits and dogs by freezing the abdominal aorta, cauterization of the vasa vasorum (Schlichter et al., 1949), injection of irritating substances into the arterial wall, and by various tearing or cutting maneuvers. When local trauma was combined with a systemic factor, such as a high-cholesterol diet, the injection of egg yolk or of a cholesterol suspension, something similar to the atherosclerotic process may result, supporting the concept that human atherosclerosis may result from changes initiated in the media.

Kidney Trauma. Nephrectomized dogs maintained for prolonged periods either by peritoneal dialysis or an artificial kidney (especially if previously fed on a high-fat diet) show degeneration

of the smooth fibers of the media and hyalinization and proliferation of the subintima; these

gery, a peculiar type of medial calcification follows, this has been attributed to the development of hyperparathyroidism secondary to the kidney insufficiency. All these experiments point to the fact that a normally functioning kidney is necessary for the maintenance of the integrity of the medial layer of the arteries.

Dietary Factors. The influence of diet in the maintenance of normal arteries has been demonstrated mainly under the following circumstances.

CHOLINE DEFICIENCY. This deficiency in rats produces medial sclerosis of the aorta and the coronary arteries which is aggravated by cholesterol feeding.

LATHYRISM. Rats and turkeys fed with seeds of *Lathyrus odorata* develop dissecting aneurysms of the aorta and bone lesions.

VITAMIN E DEFICIENCY. This deficiency in guinea pigs, but not in rats, produces medial degeneration and calcification of the aorta.

ENDOCRINE GLANDS. Rats with diabetes caused either by alloxan administration or by subtotal pancreatectomy show arteriolar hyalinization, it is possible that these changes are dependent not on the pancreas but on a secondary kidney damage.

OTHER FACTORS. The intravenous injection of allylamine into dogs induces fibrinoid necrosis of the coronary arteries as well as slight changes in the aortic intima. when egg yolk is also injected, fatty infiltration is observed and a lesion similar to human atherosclerosis may result.

From the above results it appears that, although an injury to the arterial media can be produced in many ways, the histological picture may show a great uniformity, namely, an acute inflammatory response and a repair process. Different noxious stimuli evoke a similar picture, which is apparently due to a constant pathological response of the arterial media. Consequently, it cannot always be concluded that the experimental lesions are caused by mechanisms similar to those of their clinical counterparts.

RESULTS OF EXPERIMENTAL ATHEROSCLEROSIS

Degenerative changes, mainly limited to the intima, are characteristic of atherosclerosis, extension of the changes into the media, however, are so common that many authors suggest that atherosclerosis may really start in the latter. Furthermore, although the process may seem to be primarily of a degenerative nature, the role of inflammation has not been completely ruled out in some instances (Saphir and Gore). For brevity's sake, it will be assumed that (1) the arterial changes of atherosclerosis develop primarily in the intima, and (2) inflammation is *not* a primary phenomenon in the majority of the atherosclerotic lesions.

It will be useful to review the various methods of production of atherosclerosis in different species.

Rabbit. The rabbit is the first animal in which atherosclerotic lesions have been consistently produced, the fact that the lesions were first obtained by feeding cholesterol has greatly influenced later research. Cholesterol is a foreign substance to herbivora which, after weaning, do not normally ingest this solid alcohol. When cholesterol is given in amounts varying from 250 to 1,000 mg per day for 2 or 3 months, a marked hyperlipemia and hypercholesterolemia is produced, and gross atherosclerotic lesions appear in 70 to 80 per cent of the animals; at the same time, xanthomatous deposits in the pulmonary circulation, cartilages, cornea, and liver, as well as amyloidosis of the skin, ectopic blood formation, and other signs of damage can also be found. The fact that 20 to 30 per cent of the cholesterol-fed rabbits are naturally resistant to this form of atherosclerosis must be remembered when experiments consisting of a few animals are statistically analyzed. The way in which cholesterol is given does not influence the severity of the lesions although the iodine number of the accompanying oil does influence the amount of the change. The early lesions induced by this method consist of sudanophilic droplets located in the subendothelial ground substance of the intima and may appear even before the occurrence of pronounced changes in the plasma level of lipids, alternative explanations suggest that cholesterol is first phagocyted by the endothelial lining cells and then released into the ground substance. However, the subsequent gross hypercholesterolemia undoubtedly influences the deposition of cholesterol in the intima and the subsequent arterial reactions. As a whole, it seems well established that feeding cholesterol to rabbits induces local changes in the intima and in the media (increased endothelial permeability, increased subintimal mucopolysaccharides, appearance of a phagocyting capacity of the endothelial cells) and that subsequently the cholesterol-loaded plasma, by a process of ultrafiltration, is able to cause local deposits, proliferation of foam cells, fibroblasts, and other damage. Older theories trac-

ing the foam cells to detached Kupffer cells have been discarded.

Contrary to the above-mentioned findings, marked hyperlipemia without hypercholesterolemia does not produce atherosclerosis in rabbits, thus pointing to the pathogenic role of cholesterol in this connection. Other foreign sterols, such as dihydrocholesterol, when given in sufficiently high doses, can also produce atheromatous lesions, the precipitation of foreign sterols in the arteries of rabbits, then, is apparently a nonspecific phenomenon probably related to solubility factors and other conditions.

Chicken. Chickens develop spontaneous atherosclerosis and these lesions have also been experimentally induced through cholesterol feeding, stilbestrol implantation, or dihydrocholesterol feeding. Thorough studies have been made, especially on the first of these methods. They were able to show that cholesterol-fed birds are resistant during the very early period of life, while the lesions are easily produced after the eighth week and regress spontaneously after the twentieth. This points to the importance of endogenous factors on the metabolism of exogenous cholesterol and on the subsequent arterial lesions. The same method has been used to demonstrate complex endocrinous relationships between the development of arterial lesions and the function of the adrenals, pancreas, thyroid, and gonads. An important fact that has emerged from these studies is that estrogenic substances may prevent and cause regression of coronary atherosclerosis (Katz and Stamler, 1953).

Dog. Lesions resembling atherosclerotic plaques have been produced in dogs by the intravenous injection of huge amounts of macromolecular substances (gum acacia, polyvinyl alcohol, etc.), which apparently are phagocytized by the endothelial cells True atherosclerotic lesions were produced later in cholesterol-fed, hypothyroid dogs (Steiner and Kendall) The early lesions consisted of lipid deposits in the media, between and within the cells, followed by a secondary intimal proliferation. In contrast with this, spontaneous lesions arise as early degeneration of the internal elastic membrane with a secondary proliferation of intimal connective tissue, while lipid deposits are apparently a secondary phenomenon, hypertension increases the severity of atherosclerosis in dogs.

Rat. Until recently rats have been considered to be resistant to the development of atherosclerosis. It was demonstrated that this "resistance" was not a property of the arteries themselves, since aqueous buffered suspensions of cholesterol, when injected into doubly ligated femoral arteries, produced atherosclerotic-like lesions in rats Shortly afterwards, experimentally induced generalized atherosclerosis was reported by three independent groups; later on, spontaneous atherosclerosis was described. The rat, being an omnivorous mammal with a diet similar to that of man, could be considered suitable for studies of a chronic disease Its short life span would make it quite desirable, but the minuteness of the lesions forces the researcher to rely exclusively on microscopic studies, except when synthetic diets, with a high content of cholesterol and cholate, are given to hypothyroid rats. In this case, gross aortic lesions are consistently produced. Along these lines, it has been shown that hypertension has no aggravating effect on the development of atherosclerosis and that estrogens can prevent spontaneous and experimentally induced atherosclerosis.

Cat. Spontaneous atherosclerosis in the aorta and the coronary arteries of cats has been described. The lesions apparently start as medial elastic fragmentation, lipids playing no part in the early process.

Monkey. Atherosclerosis has been produced in two types of monkeys: (1) the *rhesus*, through pyridoxine deficiency or prolonged high-fat, high-cholesterol diet, and (2) the *Cebus*, through mild deficiency of organic sulfur compounds plus a large cholesterol intake. In pyridoxine deficiency, there is an accumulation in the intima (and sometimes the media) of the abdominal aorta and the iliac arteries of a mucoid intercellular substance showing the metachromatic staining of mucopolysaccharides, there also is a proliferation of endothelial cells and elastic fibers while, in older lesions, lipoid deposits appear. When other dietary methods are used, excess lipids are deposited in the arteries, and endothelial plaques are plentiful.

Other Animals. Atherosclerosis has also been described in several other animals including the golden hamster, guinea pig, elephant, goose, mouse, thus showing that atherosclerotic lesions are not the exclusive property of any species

PATHOGENETIC MECHANISMS OF EXPERIMENTAL ATHEROSCLEROSIS; POSSIBLE CONNECTION WITH HUMAN ATHEROSCLEROSIS

The fact that atherosclerosis can be produced in many species through different methods clearly shows that these lesions can be considered to represent nonspecific end results following arterial injuries, although it must be granted that not every type of injury leads to the development of atherosclerosis Some of the initiating factors, such as pyridoxine and deficiency, stilbestrol implantation, are clearly

not connected with human atherosclerosis; others, such as high-fat diet, high-cholesterol diet, or a combination of both, have not been conclusively shown to be concerned with the initiation of lesions, while still other factors (e.g., genetic, constitutional), although probably important, are still undetermined. Nevertheless, and in spite of the lack of knowledge of the mechanisms involved in the factors responsible for the *initiation* of the atherosclerotic process, it is apparent that the *progression* of the lesions is somewhat connected with a disturbance in the metabolism of lipids, even though other factors may be involved. The factors related to the progression (and to the initiation?) of the degenerative changes can be classified as follows.

Local Factors. Arteries must not be regarded as simple tubes only able to distribute blood, but as complex organs within which complicated enzymatic reactions do take place. Furthermore, materials enter and leave the arterial walls. They are carried by fluids which follow hemodynamic laws similar to those operating in the rest of the organism: fluids ultrafilter toward the arterial wall from the intima and from the arterial side of the vasa vasorum and are subsequently reabsorbed from the artery through the venous side of the vasa vasorum, as well as from the lymphatics. This ultrafiltration must also depend on the permeability of the endothelia, the filtration pressure (arterial and capillary), the osmotic pressure, and the tissue pressure (Part 2, Chap. 18). Moreover, if lipids are transported within the arteries as they are in the intestines, the lymphatics may play an important role in the pathogenesis of atherosclerosis, a point seldom raised in this connection. It is clear that the accumulation of any substance within the arterial wall must necessarily be secondary to a disturbance of the intramural circulation, of the local metabolism of the substances normally carried to the artery, or both. As a consequence, atherosclerotic plaques, which represent the accumulation of different lipids within the arterial walls (cholesterol, phospholipids, and neutral fats) could be the result of the following factors: (1) an increased input load, due to higher plasma levels or greater velocity of filtration, caused by either higher pressure or increased permeability of the endothelia, (2) an increased local synthesis, (3) a decreased local utilization; (4) a decreased removal due to local precipitation through physical instability or disturbance in the reabsorbing system; or (5) a variable combination of these processes.

Increased plasma-cholesterol level is only one of the many factors which lead to accumulation of this material within the arterial walls. This explains the many examples of atherosclerosis in spite of a normal cholesterolemia. Furthermore, it must be remembered that most of the clinical importance of atherosclerosis is related to the obstruction of the blood flow effected by this process. The formation of intimal plaques is only one of the mechanisms which may ultimately lead to the "atheromatous obstruction" of an artery. Consideration must also be given in this connection to local thrombus formation, intramural hemorrhage, and vascular muscular contraction.

General Factors. General factors, such as hypercholesterolemia, hypertension, diabetes, and sex, which are related to the progression (and the *initiation?*) of atherosclerosis, must *necessarily influence* the plaques through a modification of the local factors already mentioned.

DISTURBED LIPID METABOLISM. High blood lipid levels, indicative of a disturbed general lipid metabolism, are connected with an *acceleration* of atherosclerosis, although not all lipids share similar actions. An elevated blood-cholesterol level is necessary for the development or the acceleration of atherosclerosis in some animals (rabbits, dogs, chickens, monkeys) but not in others (rats). In rabbits, elevated levels are apparently secondary to a failure of the hepatic Kupffer cells to dispose of the absorbed intestinal cholesterol and to transfer it to the liver cells. In man, the cholesterol synthesized from the acetyl coenzyme A formed during metabolism is probably more important than exogenous cholesterol. Furthermore, synthesis in the arteries may also contribute to the local accumulation of the atheromatous plaques. Induced high blood levels of *neutral fats*, even when accompanied by a moderate increase in cholesterol level, are not connected with an accelerated atherogenesis; this suggests that cholesterol is solubilized in the neutral fat. Heparin, which clears postprandial lipemic blood and activates a lipolytic enzymatic system in the plasma, has been re-

ported to decrease cholesterol-induced atherosclerosis in rabbits. High *phospholipid* levels apparently are able to protect animals from the development of atherosclerosis, and this is also explained as due to a solubilizing effect. Furthermore, attention has been drawn, not only to the absolute levels attained by individual lipids in the blood, but also to their physicochemical distribution. Lipids are not soluble in plasma and are transported as complex combinations with the plasma proteins. It has been postulated that not all these lipoproteins share the same "atherogenic" action, this being maximal for the S_f 12 to 400 lipoproteins[1] (Gofman, 1950) This concept has been questioned in individual cases and it has been suggested that more useful information can be gathered from the level of blood cholesterol. As already pointed out, hypercholesterolemia is just *one* factor which may lead to increased cholesterol deposition within the arterial walls.

HYPERTENSION. The clinical observation that hypertension accelerates atherogenesis has been confirmed in several kinds of animals (rabbits, dogs, and chickens). In rats, however, hypertension does not seem to influence atherosclerosis.

SEX. The gonadal hormones are able to influence experimental atherosclerosis, but the results are not the same in different animals. Most studies have been conducted with female hormones, following the studies of Pick Diethylstilbestrol increases aortic atherosclerosis while estradiol benzoate prevents or causes regression of coronary atherosclerosis in cholesterol-fed chickens. A somewhat similar situation exists in rats, where estradiol benzoate cannot prevent coronary atherosclerosis in nephritic rats on high-fat diets, but prevents the development of spontaneous atherosclerosis in other parts of the vascular system In rabbits, both estrogens and testosterone can prevent atherogenesis in the female, but not in the male. In man, estrogenic substances decrease coronary atherosclerosis

PARTS OF THE ARTERIAL SYSTEM. Besides the stated difference between systemic and pulmonary circulation, experimental atherogenesis does not proceed in a parallel way in all parts of the systemic circulation. For instance, estrogens increase atherosclerosis *in the aorta* while decreasing the lesions *in the coronary system* of cholesterol-fed chickens. The same estrogenic substances can prevent atherogenesis under certain circumstances in the aortic collateral arteries but not in the coronary arteries of perinephritic rats. These experiments again point to the importance of local factors and class differences in the genesis of arterial lesions.

In summary then, the pathogenesis of the arterial intimal lesions is not known. From the fact that they can be produced by different methods, they can be considered as representing nonspecific end results caused by several noxious stimuli, the reaction of the arterial wall being regulated by the interplay of local and general factors One of the many possible noxious stimuli acting in this connection is an abnormal metabolism of the lipids, chiefly cholesterol. This leads to increased deposition of cholesterol in the arterial walls and eventually causes a localized tissue reaction, *the atheromatous plaque.*

THERAPY OF EXPERIMENTAL ATHEROSCLEROSIS

An important fact which has emerged from research is that atherosclerotic lesions can be prevented or may regress under favorable circumstances Of course, experimental results obtained in one species and by the use of a particular method cannot always be applied to another species in which atherogenesis may follow a totally different method

In interpreting results of "curative" drugs in connection with atherosclerosis, other points must be taken into consideration. For instance, when cholesterol is given, it must be determined if it is actually ingested when given in combination with another drug which may be offensive to the animal or interfere with its eating (unpalatable) or sleeping habits. Another complicating factor is the total quantity of calories ingested, since undernutrition may increase or decrease atherogenesis in different species of animals.

Iodides and Thyroid Hormones. Desiccated thyroid gland decreases atherogenesis in chickens while iodine, which had been reported as protecting rabbits against cholesterol-induced atherogenesis, has been demonstrated to be without effect.

[1] S_f is the symbol for *Svedberg unit of flotation*

Lipotropic Agents. Lipotropic agents have consistently failed to alter experimental and spontaneous atherogenesis in rabbits and chickens

Heparin. Heparin, which is able to activate a lipolytic system in the blood, has been tested in the treatment of experimental atherosclerosis The results are somewhat conflicting since it has been reported that heparin does not prevent atherogenesis in the rabbit or in the chicken, although it seems that, under certain conditions, it can prevent it in other cholesterol-fed animals.

Estrogens. Estrogens have successfully prevented coronary atherosclerosis in cholesterol-fed chickens, and these results have been confirmed in rats, in which they are also effective in other parts of the arterial tree. In female, but not in male cholesterol-fed rabbits, estrogens or testosterone can prevent aortic atherogenesis The mechanisms involved are not clear in this species since some authors believe that the preventive action is mediated through the ovaries, while others state that castrated female rabbits show less atherosclerosis than nonoperated controls

Other Factors. Attempts to prevent absorption of intestinal cholesterol have been reported successful in decreasing atherogenesis in cholesterol-fed rabbits and chickens. A cholesterol-free brain fraction, which apparently is able to promote the conversion of the absorbable cholesterol into nonabsorbable coprosterol, decreases atherosclerosis in chickens. *Sitosterol*, which apparently competes with intestinal cholesterol for enzymatic esterification and subsequent reabsorption, seems to prevent atherogenesis in cholesterol-fed rabbits and chickens Finally, *dihydrocholesterol* (an alcohol greatly resembling cholesterol) can prevent the intestinal absorption of cholesterol and the subsequent atherosclerosis in cholesterol-fed rabbits and chickens, even though prolonged administration of this sterol induces atherosclerosis in the latter.

Other substances have been reported to have various results in the treatment of cholesterol-induced atherosclerosis, such as gallogen, elastase, ferric chloride, and adenyl monophosphate Some of these have already been discarded, others must be further evaluated Nevertheless, since practically all are tested against cholesterol-induced atherosclerosis, a similarity of the mechanisms of experimental and human atherosclerosis should be demonstrated before they can be applied to man.

Biochemistry of arteriosclerosis

JOHN W. GOFMAN

A subject such as the biochemistry of arteriosclerosis can be approached in two different ways. The first is the encyclopedic approach of listing the contributions to biochemical morphology of the arteriosclerotic lesion. This provides a recapitulation of important contributions of investigators, past and present, throughout the world, but has no real value to the practicing physician. The second is to seek out those features of the biochemistry of arteriosclerosis which lend themselves to the formulation of a reasonable "model" of the development of arteriosclerosis that may be meaningful in clinical medicine.

Perhaps in a set of volumes such as these it is necessary to review what is meant by a "model." By this is *not* meant a final, completed concept of a thoroughly understood phenomenon, but rather what appears to be a reasonable construct of the biochemical features of the disease, integrated into a formulation that allows clinicians and researchers alike to go forward with further studies and evaluations. A "model" is set up as a target for criticism, for tests of consistency with reality (as revealed by observational medicine), and for modification. Such a "model" is not created out of sheer speculation, but with some imagination utilized to weave together a body of solidly established biochemical and clinical *facts* concerning the disease under study, here arteriosclerosis. This weaving is necessarily imperfect for, if *every* facet of *every* part of the problem were completely understood, no weaving would be necessary; one could instead be completely encyclopedic. Thus, it is the hope of the author that the following biochemical "model" of arteriosclerosis will serve as a target for the critical analysts of the problem, who will be able to detect where the weaving together of certain observational *facts* has been imperfect and where a reweaving can serve to improve the model, so that it can better serve our ultimate goal—an understanding of the evolution of arteriosclerosis which can aid medicine in its prevention or minimization.

THE LESION

Two subjects are of real consequence in a discussion of the arteriosclerotic lesion: (1) its structural features of importance; (2) its focal character.

The chemical, histochemical, histological, and gross anatomic features of arteriosclerosis have been intimately described (Chaps. 1, 2, 3). That lipid alterations, mucopolysaccharide alterations, fibrosis, elastic-tissue changes, thrombosis, hemorrhage, and calcification are all important structural elements is not to be questioned, they represent observational facts. How these structural features mesh together is today a matter of speculation and a challenge for further work. However, these structural elements of the arteriosclerotic lesion do mesh together and, whatever the primary or initiating cause of the lesion, it is clear that the clinical consequences of arteriosclerosis are felt when one or more of these structural elements has led to an appreciable *degree of narrowing* of the arterial lumen, be it in the coronary, the cerebral, or the peripheral arterial tree. The nomenclature of Goldblatt, i.e., *simple intimal arteriosclerosis,* encompasses those lesions in important areas of the arterial tree which are productive of luminal encroachment and have ultimate clinical consequences, and avoids the fruitless arguments (fruitless at this time) as to which structural elements

are primary or of more importance than others The lesion of interest is that which leads to clinical consequences and, hence, the final concept of primacy or importance of structural features must meet the test of consistency with clinical, observational reality. Luminal narrowing, acute or chronic, appears to meet such a test at present Most other features have hardly even been considered.

The *focal* character of arteriosclerosis is clearly a reality to any observer. No one can doubt the truth of the statement that one region of a particular arterial bed may be more extensively diseased than the region a centimeter farther along the same artery, or can doubt that, at times, one arterial bed itself, e g., the coronary bed, can be extensively diseased while another will be but little involved. Unfortunately these facts have been widely misused to confuse the physician about two critical features of the development of arteriosclerosis First, while intimal arteriosclerosis is characterized by an ability to manifest major *focal* features, there does exist a tendency for the degrees of involvement of various parts of a single arterial bed, as well as for the degrees of involvement of widely separated arterial beds, *to rise and fall together* Second (and in part a corollary to the first point), the focal character of the arteriosclerotic lesion *in no way* militates against the evidence, now difficult to assail, that general metabolic features operate to determine the degree of arteriosclerotic involvement of muscular and large arteries in arterial beds throughout the body.

Every effort must be encouraged to delineate the important features which are determinative of the focalization of the lesion Proposals that mechanical or anatomic factors (such as kinking, local wall defects, or elastic tissue degeneration) or toxic factors (such as the action of catechol amines) are major elements in human intimal arteriosclerosis are dubious ones that need to be decided in the early future. Further work will undoubtedly help in this area, for no definitive case has yet been made out for any of them

Whatever the ultimate solution of the problem of focalization, there is no conflict of this aspect of the problem with that of the general metabolic features of the development of this disease There seems to be little reason to doubt that focal factors would be of minor moment in the production of arteriosclerosis if the intensity of the general metabolic predisposing influences could be brought under control. This is hardly equivalent to the statement that arteriosclerosis would be completely prevented if the general metabolic influences were controlled. *Rather, such an event would grossly reduce the incidence of development of lesions of sufficient consequence to produce widespread clinical manifestations.*

GENERAL FACTORS INVOLVED IN PRODUCTION OF THE LESION

It is in the area of general factors involved in the production of the arteriosclerotic lesion that methods have been developed over the years that allow for approaches to the clinical consequences of the lesion These consequences have been elucidated in three major ways over the years:

1. By experimental induction of lesions in animals that simulate closely many features of the human lesion

2 By direct study in human beings of clinical entities that are consequences of arteriosclerosis, especially coronary heart disease, arteriosclerosis obliterans, and cerebrovascular disease

3. By pathological studies of the human arteriosclerotic lesion in various vascular beds.

Out of such studies certain conclusions can be drawn; these appear safely established and are unlikely to change in the course of further integration of existing knowledge with new observational material Arteriosclerosis in the human being is a *progressive, cumulative disease*, that is extremely widespread in populations throughout the world, with great variability in the extent of its development characterizing certain population subgroups, e g., males of a particular age in a single geographic locale. The pathological character of the lesion at any moment is the sum of the fresh increments to the lesion plus older increments that have undergone certain changes during the course of their existence within the arterial wall The net effect of all such increments, new and old, is production of an encroachment upon the arterial lumen. No reason exists to differentiate intimal arteriosclerosis in young individuals from intimal arteriosclerosis in old individuals. Any existing difference resides primarily in the altered proportions of relatively

fresh increments in comparison with older ones. Reversibility of the arteriosclerotic lesion is clearly established in experimental animals and, by indirect evidence, appears to be a highly probable occurrence in human beings as well. So-called *episodic* development of human arteriosclerosis seems to be the result of periodic accelerations in the rate of development of the lesions, over and above a steady cumulative process.

Inasmuch as arteriosclerosis is *a cumulative process over time*, there must exist at least one *rate factor* which is important. It can be anticipated that a high *rate* of cumulation will result in extensive disease development in relatively few years, a low rate of cumulation would mean that many more years would be required to produce the same development of lesions A most profitable approach to the biochemistry of arteriosclerosis is to seek out factors that may determine, in part or in whole, *the rate of development of the lesion* A host of factors has been considered, suspected, and speculated upon, but only two have remained which are definitively implicated as rate factors in the development of arteriosclerosis: (1) the level of certain blood lipids; and (2) the level of the blood pressure These are *independent* rate factors in the development of arteriosclerosis. By this is meant that each provides information concerning the rate of lesion development over and above information provided by the other. Thus, if two persons were identical with respect to the crucial blood lipids, but one showed a higher diastolic blood pressure than the other, the rate of arteriosclerosis development would be higher in the former in proportion to the elevation in blood pressure. Conversely, if two persons were identical with respect to habitual blood pressure, but one showed a higher level of the crucial blood lipids than the other, the rate of development of arteriosclerosis would be higher in the former person in proportion to the degree of elevation in the level of the blood lipids It is of interest to note that the concept of arteriosclerosis presented here is essentially that proposed by Virchow many years ago, namely that filtration of blood lipids probably initiates the arteriosclerotic lesion, abetted by the pressure of the blood in the vascular lumen. Virchow's astute suggestion was made in the absence of a great deal of substantiating data, clinical or experimental, simply because it appeared reasonable to him After many decades of relatively barren wandering in this medical area, investigators admit that multiple evidence provides a firm support for Virchow's original concept.

THE BLOOD LIPID FACTOR

It was stated above that only certain blood lipids are of crucial importance in determining the rate of development of arteriosclerosis. This is verified by direct observation that indeed certain other blood lipids are either (1) *uninvolved* in the development of arteriosclerosis or (2) possibly *inversely related* to the development of arteriosclerosis. Essentially, all the lipids in the blood exist in the form of macromolecular complexes either with polypeptides or proteins, and are therefore designated as *lipoproteins*. These lipoproteins may be detected and quantitated by a variety of methods, ranging from the original chemical precipitation techniques of Macheboeuf to the precise methods of *ultracentrifugation*. Between these extremes there is a variety of methods for identifying and quantitating the lipoproteins of blood. All are of value, but some are more crude with respect to information than others.

The cardinal fact is that certain liproproteins *exist* in blood. If these lipoproteins are assayed by a particular method, no amount of chemical, physical, or statistical maneuvering will extract additional information from that analysis of the blood lipid content. The real difference between the various methods lies in the differing extent to which they assess the blood content of the particular lipoproteins of interest in arteriosclerosis. This point deserves illustration, for few issues have more thoroughly beclouded the status of our knowledge of the relationship of blood lipids to the development of human arteriosclerosis.

Cholesterol and the *phospholipids* are two of the kinds of substances which exist in the blood wholly in the form of lipoproteins Every lipoprotein class isolated from human blood contains some cholesterol and some phospholipid The percentages of cholesterol and phospholipid differ from one lipoprotein class to another Many investigators have come to the conclusion that *high cholesterol/phospholipid ratios* are in some way associated with a high rate of development of human arterio-

sclerosis. But they have drawn the incorrect conclusion that there is something intrinsically important about the ratio of these two substances in the blood. The reason why the cholesterol/phospholipid ratio is of importance at all in arteriosclerosis (or some of its clinical sequelae) is that *there is an appreciable correlation between the cholesterol/phospholipid ratio and the levels of those low-density lipoproteins* which are intimately related to the rate of development of arteriosclerosis. However this correlation is highly imperfect. Numerous situations exist where the cholesterol/phospholipid ratio is favorable while the low-density lipoprotein pattern is highly unfavorable. In such cases, the ratio of cholesterol to phospholipid *erroneously* predicts a low rate of development of arteriosclerosis. Other situations exist where the cholesterol/...

ratio

lipop

the r

roneously predicts a high rate of development of arteriosclerosis. If one is willing to accept a certain proportion of erroneous decisions of either kind, then he may profitably use an indicator such as the cholesterol/phospholipid ratio, especially if the latter analytical result is *the only* one available. Under such circumstances, the determination of the cholesterol/phospholipid ratio is far superior to a complete failure to assess the blood lipid status. Entirely analogous reasoning applies to other methods

... cholesterol content, and the turbidity of serum. All of them are secondary methods that approximate a measure of those lipoproteins in blood that are of demonstrable importance in arteriosclerosis. If this is realized, there is no objection to the employment of any of these lipid assays in the evaluation of arteriosclerosis. Concrete evidence has been brought forth of an association between the rate of development of arteriosclerosis and the group of lipoproteins characterized ultracentrifugally as *the S_f 0 to 400 lipoproteins*, these are part of the over-all group of substances in the blood known as *low-density lipoproteins*.

Unfortunately, when electrophoretic techniques are used, these lipoproteins are labeled as beta lipoproteins under certain analytical conditions and as alpha lipoproteins under other conditions. Under still other conditions, electrophoretic analysis completely misses some of the S_f 0 to 400 lipoproteins, either as beta or alpha lipoproteins. Hence, if electrophoretic classification is to be used at all, it is imperative that the conditions be precisely defined, if two investigators are desirous of comparing the results of their respective investigations of arteriosclerosis.

Ultracentrifuge methods, under standard conditions, are free of the various difficulties inherent in the more crude methods described above. A *direct* assay of the lipoproteins *in the S_f 0 to 400* band is readily available through ultracentrifuga-

cation will become available through some other technique in the future, possibly even the early future. However at present, no method provides the requisite information as directly as do the methods involving the ultracentrifuge.

Utilizing coronary heart disease and arteriosclerosis obliterans as criteria for arteriosclerosis of their respective arterial beds, it has been shown that the levels of the S_f 0 to 400 lipoproteins are directly related to the *rate* of development of arteriosclerosis. The relative importance of various subclasses of lipoproteins within the S_f 0 to 400 band is still subject to revision as additional evidence becomes available. For *coronary arteriosclerosis, the best estimate indicates that the S_f 12 to 400 segment is approximately one and one-half to two times as important, milligram for milligram, as the S_f 0 to 12 lipoprotein segment.* This has led to the formulation of a combined value which allows for this weighted importance of the two subclasses, *the atherogenic index*. *Atherogenic index is* defined as equal to

$$\frac{L_1 \text{ (in mg/100 ml)} + 1.75\ L_2 \text{ (in mg/100 ml)}}{10}$$

where L_1 = lipoproteins of S_f 0 to 12

L_2 = lipoproteins of S_f 12 to 400

That both lipoprotein classes (S_f 0 to 12 and S_f 12 to 400) are of independent importance as determinants of the rate of development of human arteriosclerosis is quite clear. That the 1.75 factor for weighting the S_f 12 to 400 lipoproteins is subject to revision is also quite clear. Furthermore, it is possible that the relative weighting factor may be different for arteriosclerosis in *one* arterial bed as com-

fresh increments in comparison with older ones. Reversibility of the arteriosclerotic lesion is clearly established in experimental animals and, by indirect evidence, appears to be a highly probable occurrence in human beings as well. So-called *episodic* development of human arteriosclerosis seems to be the result of periodic accelerations in the rate of development of the lesions, over and above a steady cumulative process

Inasmuch as arteriosclerosis is *a cumulative process over time*, there must exist at least one *rate factor* which is important. It can be anticipated that a high *rate* of cumulation will result in extensive disease development in relatively few years, a low rate of cumulation would mean that many more years would be required to produce the same development of lesions A most profitable approach to the biochemistry of arteriosclerosis is to seek out factors that may determine, in part or in whole, *the rate of development of the lesion* A host of factors has been considered, suspected, and speculated upon, but only two have remained which are definitively implicated as rate factors in the development of arteriosclerosis. (1) the level of certain blood lipids, and (2) the level of the blood pressure These are *independent* rate factors in the development of arteriosclerosis By this is meant that each provides information concerning the rate of lesion development over and above information provided by the other. Thus, if two persons were identical with respect to the crucial blood lipids, but one showed a higher diastolic blood pressure than the other, the rate of arteriosclerosis development would be higher in the former in proportion to the elevation in blood pressure. Conversely, if two persons were identical with respect to habitual blood pressure, but one showed a higher level of the crucial blood lipids than the other, the rate of development of arteriosclerosis would be higher in the former person in proportion to the degree of elevation in the level of the blood lipids. It is of interest to note that the concept of arteriosclerosis presented here is essentially that proposed by Virchow many years ago; namely that filtration of blood lipids probably initiates the arteriosclerotic lesion, abetted by the pressure of the blood in the vascular lumen. Virchow's astute suggestion was made in the absence of a great deal of substantiating data, clinical or experimental, simply because it appeared reasonable to him After many decades of relatively barren wandering in this medical area, investigators admit that multiple evidence provides a firm support for Virchow's original concept.

THE BLOOD LIPID FACTOR

It was stated above that only certain blood lipids are of crucial importance in determining the rate of development of arteriosclerosis This is verified by direct observation that indeed certain other blood lipids are either (1) *uninvolved* in the development of arteriosclerosis or (2) possibly *inversely related* to the development of arteriosclerosis. Essentially, all the lipids in the blood exist in the form of macromolecular complexes either with polypeptides or proteins, and are therefore designated as *lipoproteins*. These lipoproteins may be detected and quantitated by a variety of methods, ranging from the original chemical precipitation techniques of Macheboeuf to the precise methods of *ultracentrifugation*. Between these extremes there is a variety of methods for identifying and quantitating the lipoproteins of blood. All are of value, but some are more crude with respect to information than others

The cardinal fact is that certain liproproteins *exist* in blood. If these lipoproteins are assayed by a particular method, no amount of chemical, physical, or statistical maneuvering will extract additional information from that analysis of the blood lipid content. The real difference between the various methods lies in the differing extent to which they assess the blood content of the particular lipoproteins of interest in arteriosclerosis. This point deserves illustration, for few issues have more thoroughly beclouded the status of our knowledge of the relationship of blood lipids to the development of human arteriosclerosis

Cholesterol and the *phospholipids* are two of the kinds of substances which exist in the blood wholly in the form of lipoproteins Every lipoprotein class isolated from human blood contains some cholesterol and some phospholipid. The percentages of cholesterol and phospholipid differ from one lipoprotein class to another. Many investigators have come to the conclusion that *high cholesterol/phospholipid ratios* are in some way associated with a high rate of development of human arterio-

sclerosis. But they have drawn the incorrect conclusion that there is something intrinsically important about the ratio of these two substances in the blood. The reason why the cholesterol/phospholipid ratio is of importance at all in arteriosclerosis (or some of its clinical sequelae) is that *there is an appreciable correlation between the cholesterol/phospholipid ratio and the levels of those low-density lipoproteins* which are intimately related to the rate of development of arteriosclerosis. However this correlation is highly imperfect. Numerous situations exist where the cholesterol/phospholipid ratio is favorable while the low-density lipoprotein pattern is highly unfavorable. In such cases, the ratio of cholesterol to phospholipid *erroneously* predicts a low rate of development of arteriosclerosis *Other situations* exist where the cholesterol/phospholipid ratio is very unfavorable while the low-density lipoprotein pattern is favorable. In such cases, the ratio of cholesterol to phospholipid *erroneously* predicts a high rate of development of arteriosclerosis If one is willing to accept a certain proportion of erroneous decisions of either kind, then he may profitably use an indicator such as the cholesterol/phospholipid ratio, especially if the latter analytical result is the only one available Under such circumstances, the determination of the cholesterol/phospholipid ratio is far superior to a complete failure to assess the blood lipid status Entirely analogous reasoning applies to other methods, such as a determination of the blood cholesterol content [illegible] bet[illegible] ble [illegible], and the turbidity of serum. All of them are secondary methods that approximate a measure of those lipoproteins in blood that are of demonstrable importance in arteriosclerosis If this is realized, there is no objection to the employment of any of these lipid assays in the evaluation of arteriosclerosis Concrete evidence has been brought forth of an association between the rate of development of arteriosclerosis and the group of lipoproteins characterized ultracentrifugally as the *S_f 0 to 400 lipoproteins*, these are part of the over-all group of substances in the blood known as *low-density lipoproteins*

Unfortunately, when electrophoretic techniques are used, these lipoproteins are labeled as beta lipoproteins under certain analytical conditions and as alpha lipoproteins under other conditions. Under still other conditions, electrophoretic analysis completely misses some of the S_f 0 to 400 lipoproteins, either as beta or alpha lipoproteins. Hence, if electrophoretic classification is to be used at all, it is imperative that the conditions be precisely defined, if two investigators are desirous of comparing the results of their respective investigations of arteriosclerosis

Ultracentrifuge methods, under standard conditions, are free of the various difficulties *inherent* in the more crude methods described above A *direct* assay of the lipoproteins in the S_f 0 to 400 band is readily available through ultracentrifugation. It can hardly be claimed that this method is the best that may possibly be devised for assaying the important lipoproteins. Possibly gross simplification will become available through some other technique in the future, possibly even the early future. However at present, no method provides the requisite information as directly as do the methods involving the ultracentrifuge.

Utilizing coronary heart disease and arteriosclerosis obliterans as criteria for arteriosclerosis of their respective arterial beds, it has been shown that the levels of the S_f 0 to 400 lipoproteins are directly related to the rate of development of arteriosclerosis. The relative importance of various subclasses of lipoproteins within the S_f 0 to 400 band is still subject to revision as additional evidence becomes available For *coronary arteriosclerosis, the best estimate indicates that the S_f 12 to 400 segment is approximately one and one-half to two times as important, milligram for milligram, as the S_f 0 to 12 lipoprotein segment.* This has led to the formulation of a combined value which allows for this weighted importance of the two subclasses, *the atherogenic index*. Atherogenic index is defined as equal to

$$\frac{L_1 \text{ (in mg/100 ml)} + 1.75\ L_2 \text{ (in mg/100 ml)}}{10}$$

where L_1 = lipoproteins of S_f 0 to 12

L_2 = lipoproteins of S_f 12 to 400

That both lipoprotein classes (S_f 0 to 12 and S_f 12 to 400) are of independent importance as determinants of the rate of development of human arteriosclerosis is quite clear. That the 1.75 factor for weighting the S_f 12 to 400 lipoproteins is subject to revision is also quite clear. Furthermore, it is possible that the relative weighting factor may be different for arteriosclerosis in one arterial bed as com-

fresh increments in comparison with older ones. Reversibility of the arteriosclerotic lesion is clearly established in experimental animals and, by indirect evidence, appears to be a highly probable occurrence in human beings as well. So-called *episodic* development of human arteriosclerosis seems to be the result of periodic accelerations in the rate of development of the lesions, over and above a steady cumulative process.

Inasmuch as arteriosclerosis is *a cumulative process over time*, there must exist at least one *rate factor* which is important. It can be anticipated that a high *rate* of cumulation will result in extensive disease development in relatively few years; a low rate of cumulation would mean that many more years would be required to produce the same development of lesions A most profitable approach to the biochemistry of arteriosclerosis is to seek out factors that may determine, in part or in whole, *the rate of development of the lesion* A host of factors has been considered, suspected, and speculated upon, but only two have remained which are definitively implicated as rate factors in the development of arteriosclerosis: (1) the level of certain blood lipids, and (2) the level of the blood pressure These are *independent* rate factors in the development of arteriosclerosis. By this is meant that each provides information concerning the rate of lesion development over and above information provided by the other. Thus, *if two persons were* identical with respect to the crucial blood lipids, but one showed a higher diastolic blood pressure than the other, the rate of arteriosclerosis development would be higher in the former in proportion to the elevation in blood pressure. Conversely, if two persons were identical with respect to habitual blood pressure, but one showed a higher level of the crucial blood lipids than the other, the rate of development of arteriosclerosis would be higher in the former person in proportion to the degree of elevation in the level of the blood lipids. It is of interest to note that the concept of arteriosclerosis presented here is essentially that proposed by Virchow many years ago; namely that filtration of blood lipids probably initiates the arteriosclerotic lesion, abetted by the pressure of the blood in the vascular lumen. Virchow's astute suggestion was made in the absence of a great deal of substantiating data, clinical or experimental, simply because it appeared reasonable to him After many decades of relatively barren wandering in this medical area, investigators admit that multiple evidence provides a firm support for Virchow's original concept.

THE BLOOD LIPID FACTOR

It was stated above that only certain blood lipids are of crucial importance in determining the rate of development of arteriosclerosis This is verified by direct observation that indeed certain other blood lipids are either (1) *uninvolved* in the development of arteriosclerosis or (2) possibly *inversely related* to the development of arteriosclerosis. Essentially, all the lipids in the blood exist in the form of macromolecular complexes either with polypeptides or proteins, and are therefore designated as *lipoproteins.* These lipoproteins may be detected and quantitated by a variety of methods, ranging from the original chemical precipitation techniques of Macheboeuf to the precise methods of *ultracentrifugation*. Between these extremes there is a variety of methods for identifying and quantitating the lipoproteins of blood. All are of value, but some are more crude with respect to information than others

The cardinal fact is that certain liproproteins *exist* in blood. If these lipoproteins are assayed by a particular method, no amount of chemical, physical, or statistical maneuvering will *extract additional information* from that analysis of the blood lipid content. The real difference between the various methods lies in the differing extent to which they assess the blood content of the particular lipoproteins of interest in arteriosclerosis. This point deserves illustration, for few issues have more thoroughly beclouded the status of our knowledge of the relationship of blood lipids to the development of human arteriosclerosis.

Cholesterol and the *phospholipids* are two of the kinds of substances which exist in the blood wholly in the form of lipoproteins Every lipoprotein class isolated from human blood contains some cholesterol and some phospholipid The percentages of cholesterol and phospholipid differ from one lipoprotein class to another. Many investigators have come to the conclusion that *high cholesterol/phospholipid ratios* are in some way associated with a high rate of development of human arterio-

or wholly explainable by the proved observations that, on the average, *women present lower lipoprotein and blood pressure levels early in adult life than do men, equal levels somewhat later in life, and higher levels than men in the late decades of life.*

Age. The extent of arteriosclerosis and the incidence of coronary heart disease rise progressively with increasing age, in both the men and women. This is almost wholly or wholly explained by the *cumulative* operation of both the blood lipoprotein and blood pressure factors over a period of years

Family History. That certain families are characterized by excessive rates of development of arteriosclerosis and a high incidence rate of coronary heart disease can readily be documented It has been shown in studies of a cross section of the population that a history of premature heart disease in the father is associated with an elevation in atherogenic index and, to a much lesser extent, with an elevation in the average diastolic blood pressure of the offspring These effects operate, not only in families with extreme blood lipid disorders, but also in those with more moderate ranges of blood lipoprotein levels

Overweight. The studies of Dublin and of Dauber show a higher incidence rate of coronary heart disease in overweight persons than in those of ideal, or less than ideal, weight Furthermore, pathological studies show a higher quantitative degree of coronary arteriosclerosis in overweight persons than in nonoverweight persons All these findings are quantitatively explainable by the combination of the effect of overweight in raising both the average value of the atherogenic index and the average blood pressure level. No evidence has been brought forward to implicate the overweight per se as a mechanical-load factor in the explanation of these phenomena.

Diet. Dietary factors have been implicated, from a variety of sources of evidence, in the development of arteriosclerosis and clinical coronary heart disease Essentially all investigators in this area are convinced that dietary effects are primarily mediated by the effects of certain dietary constituents upon the levels of several lipoprotein classes Some suspicion exists that perhaps diet may also operate partly by an effect upon blood coagulability. Diet can influence blood pressure levels as well

Two major classes of foodstuffs have been indicted for their effect upon blood lipid levels: (1) the *saturated animal and vegetable fats,* both of which can increase the S_f 0 to 12 and S_f 12 to 20 lipoprotein levels (and thereby the blood cholesterol level); and (2) *the carbohydrates,* which can increase the S_f 20 to 100 and S_f 100 to 400 lipoprotein levels (and thereby the total blood lipid level). It has been proved conclusively that these two dietary elements are the responsible agents, not the caloric intake they represent.

Cigarette Smoking. Hammond and Horn have conclusively shown that the incidence of clinical coronary heart disease is appreciably higher in regular *cigarette smokers* than in nonsmokers. This effect is almost wholly or wholly explained by (1) an association of *elevation of the atherogenic index* with regular cigarette smoking; and (2) by the acute effect (during smoking) of cigarettes upon blood pressure levels. There is no chronic, sustained effect of cigarette smoking on average blood pressure levels. The effect of cigarette smoking upon the serum lipoprotein level and atherogenic index appears reversible, since those who have spontaneously ceased smoking cigarettes show blood lipid levels indistinguishable from those of persons who have never smoked. It is of interest that the studies of Hammond and Horn show that cigarette smokers who have ceased smoking regain part of the protection against coronary heart disease which characterizes nonsmokers. Since some of the accumulated coronary arteriosclerosis is most likely irreversible, it is readily understood why former smokers do not regain *all* the protection possessed by nonsmokers, even though their lipoprotein levels revert to those of the latter

Diabetes Mellitus. The quantitative increase in the incidence of coronary heart disease in diabetics as compared to the population at large and the relatively greater magnitude of this increase in the diabetic woman compared [illegible]

[illegible] lipoprotein–atherogenic index elevation and blood pressure elevation in diabetics, contrasted with the population at large. In severe decontrol with acidosis, diabetic patients in general show *massive* elevations in the blood content of several lipoprotein classes

pared with another, e.g , coronary versus peripheral.

THE BLOOD PRESSURE FACTOR

Virchow long ago had theorized that, the higher the blood pressure, the higher would be the rate of filtration of lipids from the blood into the arterial wall, and hence the greater the rate of development of arteriosclerosis. Whether or not his surmise concerning filtration was correct, clear-cut evidence now supports his concept that the higher the blood pressure, the greater is the rate of development of arteriosclerosis. This evidence has been gathered in three areas of research:

1 Experimental animal research, both in the dog and the rabbit, has demonstrated that, all other factors being equal, the rate of development of arteriosclerotic lesions varies directly with the arterial blood pressure level.

2 The careful study of a major clinical consequence of coronary arteriosclerosis, namely coronary heart disease, has led to the same conclusion by several investigators; i.e , the higher the blood pressure, the greater the risk of future clinical coronary heart disease. Taken together with the other pertinent evidence, the most reasonable basis for these observations is that elevation of blood pressure accelerates the rate of development of coronary arteriosclerosis.

3. It has been demonstrated most directly in the human being by Young et al. that, the higher the blood pressure is during life, the greater will be the extent of arteriosclerosis found postmortem in both the coronary and the cerebral arteries. Indeed, considering the *variability* of blood pressure measurements, the extent of quantitative relationship between degree of arteriosclerosis and blood pressure level is great

COMBINATION OF THE BLOOD LIPID FACTOR AND THE BLOOD PRESSURE FACTOR

In the foregoing discussion it was pointed out that (1) developing arteriosclerosis progresses, on the average, at a rate proportional *to the blood concentration* of certain lipoproteins (those within the S_f 0 to 400 class), and (2) this progression continues, on the average, at a rate proportional to the level of the diastolic blood pressure. However, on other grounds, it is known that the diastolic blood pressure is only very slightly correlated with the blood lipoprotein level. That is, a person with a high blood pressure can have low, moderate, or high lipoprotein levels, and conversely a person with a high lipoprotein level can have a low, moderate, or high blood pressure. Quantitative analysis of this problem has shown clearly that the blood pressure provides information concerning arteriosclerosis development *independent* of that provided by the lipoprotein level. The best estimate of the combined effect of both variables resides in the statement that arteriosclerosis development proceeds at a rate proportional to the *product* of the diastolic blood pressure and the lipoprotein level. It is clear, therefore, that an individual low in both multiplicative factors will show the lowest rate of development of arteriosclerosis; a person high in one factor and low in the other will show an intermediate rate; and a person high in both factors will show the highest rate of development of arteriosclerosis. Further, the advantage conferred by a low blood lipoprotein level can be quantitatively offset by a high blood pressure level, and vice versa.

OTHER FACTORS INVOLVED IN THE DEVELOPMENT OF ARTERIOSCLEROSIS

Over the years, a variety of other factors have been suspected or proved to be associated with the rate of development of human arteriosclerosis. Careful analysis of all these factors indicates that none of them can yet be shown to possess the independent status of the blood lipoprotein and the blood pressure factors The relationship of each of them to the development of arteriosclerosis has been tested with reference to the main clinical sequela of human arteriosclerosis, namely, coronary heart disease. In every case, the major share or all of the quantitative relationship of the "other factor" to coronary heart disease is explainable by its effect upon the blood lipoprotein level (as expressed in the atherogenic index formulation), the blood pressure level, or both

Sex. In early and middle adult life women show a lower degree of coronary arteriosclerosis as well as a lower incidence rate of coronary heart disease than do men. Later in life the sexes approach equality with respect to both phenomena. These facts are almost wholly

or wholly explainable by the proved observations that, on the average, *women present lower lipoprotein and blood pressure levels early in adult life than do men, equal levels somewhat later in life, and higher levels than men in the late decades of life.*

Age. The extent of arteriosclerosis and the incidence of coronary heart disease rise progressively with increasing age, in both the men and women This is almost wholly or wholly explained by the *cumulative* operation of both the blood lipoprotein and blood pressure factors over a period of years

Family History. That certain families are characterized by excessive rates of development of arteriosclerosis and a high incidence rate of coronary heart disease can readily be documented It has been shown in studies of a cross section of the population that a history of premature heart disease in the father is associated with an elevation in atherogenic index and, to a much lesser extent, with an elevation in the average diastolic blood pressure of the offspring These effects operate, not only in families with *extreme blood lipid* disorders, but also in those with more moderate ranges of blood lipoprotein levels

Overweight. The studies of Dublin and of Dauber show a higher incidence rate of coronary heart disease in overweight persons than in those of ideal, or less than ideal, weight Furthermore, pathological studies *show* a higher quantitative degree of coronary arteriosclerosis in overweight persons than in nonoverweight persons All these findings *are* quantitatively explainable by the combination of the effect of overweight in raising both the average value of the atherogenic index and the average blood pressure level No evidence has been brought forward to implicate the overweight per se as a mechanical-load factor in the explanation of these phenomena.

Diet. Dietary factors have been implicated, from a variety of sources of evidence, in the development of arteriosclerosis and clinical coronary heart disease Essentially all investigators in this area are convinced that dietary effects are primarily mediated by the effects of certain dietary constituents upon the levels of several lipoprotein classes Some suspicion exists that perhaps diet *may* also operate partly by an effect upon blood coagulability Diet can influence blood pressure levels as well

Two major classes of foodstuffs have been indicted for their effect upon blood lipid levels: (1) the *saturated animal and vegetable fats,* both of which can increase the S_f 0 to 12 and S_f 12 to 20 lipoprotein levels (and thereby the blood cholesterol level); and (2) *the carbohydrates,* which can increase the S_f 20 to 100 and S_f 100 to 400 lipoprotein levels (and thereby the total blood lipid level) It has been proved conclusively that these two dietary elements are the responsible agents, not the caloric intake they represent.

Cigarette Smoking. Hammond and Horn have conclusively shown that the incidence of clinical coronary heart disease is appreciably higher in regular *cigarette smokers than in* nonsmokers This effect is almost wholly or wholly explained by (1) an association of elevation of the atherogenic index with regular cigarette smoking; and (2) by the acute effect (during smoking) of cigarettes upon blood pressure levels There is no chronic, sustained effect of cigarette smoking on average blood pressure levels. The effect of cigarette smoking upon the serum lipoprotein level and atherogenic index appears reversible, since [illegible]

smoked. It is of interest that the studies of Hammond and Horn show that cigarette smokers who have ceased smoking regain part of the protection against coronary heart disease which characterizes nonsmokers Since *some* of the *accumulated* coronary arteriosclerosis is most likely irreversible, it is readily understood why former smokers do not regain *all* the protection possessed by nonsmokers, even though their lipoprotein levels revert to those of the latter.

Diabetes Mellitus. The quantitative increase in the incidence of coronary heart disease in diabetics as compared to the population at large and the relatively greater magnitude of this increase in the diabetic woman compared with the diabetic man are largely (and perhaps wholly) explained by the combined effects of average lipoprotein–atherogenic index elevation and blood pressure elevation in diabetics, contrasted with the population at large. In severe decontrol with acidosis, diabetic patients in general show massive elevations in the blood content of several lipoprotein classes

and of atherogenic index values, elevations which recede as acidosis and decontrol are corrected clinically. Even in the absence of clinical or chemical acidosis, it has been shown by Strisower et al. that strict chemical control of hyperglycemia and glycosuria through adequate use of insulin is, on the average, associated with lower atherogenic index values. These studies should help to resolve many emotional conflicts between the school of free diet management and the school favoring strict chemical control of diabetes.

Hypothyroidism. Severe *hypothyroidism* and *myxedema*, either spontaneous or iatrogenically induced, are characterized by marked elevation of the levels of S_f 0 to 12 and S_f 12 to 20 lipoproteins It is this elevation which accounts for the hypercholesterolemia of myxedema. In spite of claims to the contrary, there is every reason to consider the hyperlipoproteinemia (and hypercholesterolemia) of hypothyroidism to be an accelerating factor in the development of arteriosclerosis in the human being, just as would be the case in other situations where comparable elevation of blood lipid levels exists. Blumgart's contention (based upon a study of eight patients) that the hypercholesterolemia of myxedema is not an arteriosclerogenic influence has been refuted on the grounds that a number of cases ten to fifty times greater than that studied would be required even to test this concept.

Occupation. Morris' data indicate conclusively that certain occupations (in England) are characterized by incidence rates of coronary heart disease grossly higher than those for other occupations. In the main, his findings indicate that the physical activity associated with certain occupations seems to operate as a protective influence against coronary heart disease. A recent study of lipoprotein levels and blood pressure levels in 29 occupational categories of one industry has shown that there are large differences in lipoprotein–atherogenic index values between occupational categories.

Occupations involving heavy labor, such as performed by custodians and laborers, show the lowest atherogenic index values. This is consistent with Morris' contention. However, in certain occupational-group comparisons, the association of lipoprotein–atherogenic index values with the physical activity of the occupation does not appear to exist. In general, no appreciable relationship of occupational category to blood pressure level could be demonstrated; nor did responsibility, demands, and income level appear to be factors involved in determining blood-lipoprotein levels

Stress. With little in the way of quantitative measurement, a great deal of emphasis has recently been placed upon the "stresses of modern living" as a major factor determining the incidence rate of coronary heart disease Since such studies as have been reported have generally focused largely upon possible relationships of stress to blood lipid levels, the implication is a relationship of stress to development of coronary arteriosclerosis Unfortunately, no reported studies have adequately accounted for alterations in diet during periods of so-called excessive stress. In one study of accountants, a very slight (and not provably significant) elevation in mean serum cholesterol level was reported for periods of "maximal stress" versus periods of "maximal respite from stress." The very meager dietary data reported in that study indicate that what little effect (upon the serum cholesterol level) was observed could easily be accounted for by the dietary differences between the "stress" and "respite-from-stress" periods.

SUMMARY

Focal factors, little understood, do operate to determine the rate of progression of arteriosclerosis in various parts of the arterial tree The existence of focal influences is completely consistent with the existence of powerful general metabolic influences that determine the rate of development of arteriosclerosis Only *two independent general factors* have been shown to influence the rate of progression of arteriosclerosis. These are *the habitual level of certain blood lipoproteins* and *the habitual level of blood pressure.*

5

Aortic thrombosis and embolism

ELWYN EVANS

ACUTE THROMBOSIS

Etiology and Pathogenesis. Sénac (1749), according to Askey (1957), described the essential points of the current concepts of thrombosis generally credited to Virchow (1850). Both Sénac and Virchow described a triad of underlying thrombotic factors. the stimulus of damaged endothelium, the coagulability of the blood, and the degree and duration of stagnation of blood flow.

Thrombosis occurs where the endothelium is damaged by trauma, inflammation, atherosclerotic degeneration, or, *secondarily, as the* result of stasis of blood flow In the presence of *endothelial injury*, stasis increases the tendency to thrombosis by allowing more time for the interaction of thromboplastin and the other thrombotic components liberated at the *site of* injury

Because aortic thrombosis usually develops on degenerative *atheromatous lesions which* most commonly occur in the later decades of *life*, thrombotic occlusion predominantly affects the older age group Patients *in the* thromboarteriosclerotic group are on the average about 20 *years* older than those in the embolic group The ratio of males to females is about five to one.

Atherosclerosis of the aorta characteristically is most pronounced in the abdominal aorta, especially the distal portion; therefore, occlusive thromboses tend *to occur in the* narrowed lumen at or near the aortic bifurcation.

Symptoms. The symptomatology varies with the degree of preexisting stenosis *or narrowing* of the aorta (Pratt, 1954)

If sudden thrombosis occurs on an ulcerated atherosclerotic plaque, and the aortic lumen is almost normal, symptoms will be similar to those of an embolus at the aortic bifurcation. The important symptoms are almost entirely confined to the lower extremities, although, on rare occasions, a rapidly ascending occlusion will involve the mesenteric, renal, and other vessels with the appropriate *symptoms attending*. Symptoms predominantly consist of pain, anesthesia, and paralysis *Pain* occurs in about *four-fifths of the* cases, and at times radiates to the girdle or inguinal regions of the lower back. The pain varies in intensity, and is often described as excruciating, sharp, stabbing, dull, or aching (Reich, 1949). Loss of sensation *may* occur. Occasionally sensations are increased early, but later they are absent. *Weakness of the extremities* varies from slight weakness to complete paralysis and even *paraplegia*.

If a high degree of obstruction has developed slowly before acute thrombosis occurs, collateral circulation has had time to develop and ameliorate the symptoms of the acute occlusion

Signs. Signs also vary with the degree of preexisting aortic narrowing and collateral circulation *Absence of pulses is the outstanding* finding, but color and temperature changes are almost always *present*. The extremity may be black, cyanotic, mottled, pale, or white. It may be cold or clammy Reflexes may be abolished. *Varying degrees of shock* are usually present

Diagnosis. Occlusion of the abdominal aorta should be suspected when there is a sudden

onset of pain in the lower extremities and pelvis, especially when it is associated with temperature and color changes, sensory disturbances, weakness of the extremities, or paralysis. Disappearance of pulses in the femoral vessels and those below is the most important physical finding. Occasionally, the patient may go into shock or coma and expire before diagnostic signs or symptoms have had time to appear.

Acute aortic thrombosis must be differentiated from paraplegia due to other causes: poliomyelitis, transverse myelitis, peripheral neuritis, acute intraabdominal emergencies, cerebral vascular accidents, and especially embolism of the aortic bifurcation. The latter diagnosis depends primarily upon the presence of cardiac lesions which could be the source of emboli.

Prognosis. When acute thrombotic occlusions occur on ulcerated atherosclerotic plaques associated with almost normal aortic lumens, life expectancy without operation is similar to that in embolic occlusion. Often the course of acute thrombotic occlusion is milder than that of embolism because of variable degrees of preexisting stenosis and collateral circulation. The occlusion may become stabilized without loss of viability of the tissues of the extremity, then chronic arterial insufficiency develops Subsequently, development of collateral circulation may cause some gradual improvement and the appearance of the Leriche syndrome to be described later

Treatment. *Resection* of the occluded area and *grafting* should be considered in all cases. This should be done immediately if tissue necrosis or nerve damage appears evident but, if the condition appears to be mild, operation may be delayed to allow stabilization and more accurate diagnosis. DeBakey states that homografts are now obsolete, and that Dacron grafts should be used exclusively for all vessels

Caudal anesthesia or *antispasmodic drugs* may be used to help relieve vascular spasm.

CHRONIC THROMBOSIS

Several terms have been used to describe this condition including *insidious thrombosis* of the aorta and *the Leriche syndrome*. This syndrome is much more common than acute aortic thrombosis and is being recognized with increasing frequency.

Cause and Pathogenesis. As stated previously, aortic thrombosis is usually the result of thrombus formation superimposed upon atherosclerosis, and therefore is found with increasing frequency in older persons. However, chronic thrombosis of the terminal aorta at or near the bifurcation may occur in relatively young individuals. It may occur in either sex, but occurs most commonly in males between the ages of 40 and 60 years. In 24 cases operated upon by DeBakey et al. (1955c), ages ranged from 33 to 63 years, with an average age of 49 years.

Symptoms. Leriche (1923, 1940) and Leriche and Morel (1948) stated that patients, usually young men with irrelevant past histories, complained primarily either of inability to maintain a stable penile erection or of extreme fatigue of both lower extremities, instead of the well-known *intermittent claudication, extreme weariness* which came on quickly with walking and even standing, was reported.

Kirklin et al (1955) stated that partial or complete occlusion of the distal part of the aorta is characterized clinically by *distress produced by walking* and relieved by standing. Characteristically, the distress involves the thighs, regions lateral to the hips, buttocks, or rarely, the distal part of the midlumbar zone The onset is hastened when the patient walks rapidly or climbs an incline or stairs. It differs from the usual intermittent claudication involving the legs in that its location is more proximal. In rare instances, similar distress is produced by standing or exertion while standing, such as making beds or scooping grain.

Symptoms are frequently insidious in onset, but often incapacitating. Seventy-four patients with occlusion of the terminal aorta or iliac arteries were reviewed by Welch et al. (1957); of these, all complained of slowly *progressive distress* in the calf, thigh, hip, or back, induced by activity and relieved by rest This distress was described as a pain or a sensation of fatigue identical to claudication

Signs. Leriche (1923) described ischemic *pallor*, and emphasized global *atrophy* of the lower extremities without trophic lesions of

exposed parts of the skin and absence of pulses

Leriche and Morel (1948) described progressive changes extending 5 to 10 years or more: these included muscular atrophy, edema, absence of pulsation in the iliac vessels, pallor of the legs when standing and livid mottling when elevated, purplish discoloration, ecchymosis and ulcers over pressure points, and gangrene as a late manifestation. The atrophy is difficult to evaluate because a normal limb is not present for comparison.

Pataro et al. (1954) described 24 cases of aortoiliac thrombosis, in these there were marked coldness (seventeen cases), ischemic pallor (fifteen), erythromelia (four), cyanosis (six), dependent edema (one), distal lividity (one), and gangrene on the anterior part of the foot (one)

Of 47 patients with intermittent claudication of the hip and the syndrome of chronic aortoiliac thrombosis, 34 had good *extremity nutrition* and 8 fair nutrition (de Wolfe et al, 1954). Only five had poor extremity nutrition or definite trophic changes. It is of interest that three of these five patients had occlusion of the external iliac artery, *and that the other* two had involvement of the peripheral *arteries in* the lower extremities None of the patients with occlusion of the aorta or common iliac arteries had *only poor extremity nutrition*. The higher or more proximal occlusions are more likely to be associated with an adequate collateral circulation

The classic *sign is the diminution or absence of pulses in the lower extremities, and absence* of the femoral pulse is the most *important single* finding. Coelho et al (1955) *occasionally* found weak and easily *compressible* pulses in the inguinal region or below, *despite* complete aortic occlusion, these *pulses existed* because extensive collateral circulation had been established

Massarelli and Estes (1957) found the femoral artery pulse was absent in 39 *patients* and significantly *reduced in 66* Venous filling time in dependency, after *elevation of the feet*, was determined *in* 76 of their patients This was *found to* be normal in 25 patients and prolonged in 51.

Beckwith et al. (1958) *found a fairly* good correlation between the *intensity of the femoral* pulse, as determined by palpation, and the degree of occlusion above Poupart's ligament, as indicated by either aortography or gross pathological examination. *However, an absent femoral pulse did not indicate complete occlusion in all cases* Because of adequate collateral circulation, the pulses of the posterior tibial or the dorsalis pedis arteries were occasionally observed in patients with absent *femoral pulses.*

Massarelli and Estes described *bruits* over the abdominal aorta or iliac or femoral arteries in 12 cases in which they were mentioned. Beckwith et al. noted a bruit in the umbilical region or over the femoral arteries in 21 per cent of 65 cases.

Technical Studies. ROENTGENOGRAPHY. Plain x-ray films are not very helpful. Calcification of the aorta or pelvic vessels was noted in only 19 of 45 patients studied roentgenographically by de Wolfe et al (1954). When calcification was present, it was merely *confirmatory, and did* not necessarily correspond to the site of occlusion shown by aortography. Massarelli and Estes (1957) found evidence of calcification of the abdominal aorta in 37 of 105 patients, in several of whom it was discovered on reexamination of the films after negative roentgenographic reports.

OSCILLOMETRY. Oscillometric pulsations are *usually absent in the lower extremities*, but *may be detectable* in the thigh, despite absent *femoral pulsations*, because *of large collateral vessels*

AORTOGRAPHY Translumbar aortography, *introduced by dos Santos et al. (1929)*, fell into *disrepute in the United* States because of *permanent* vascular damage and death seen in experimental studies on dogs. The procedure *was revived* after extensive clinical *studies in urology* by Nelson (1942) and *Doss* (1942). Price and Wagner (1947) *first reported* its use in the diagnosis of aortic thrombosis. In recent *years*, the development of vascular *surgery* has been a *great impetus* for its widespread use.

Although *aortograms* have been widely used *in many medical* centers without serious ill effects, a *few authors* have *reported* abandoning its use because of *the* occasional reported *fatalities* and few *serious reactions* such as *paraplegia. Grossman* and Kirtley (1958) stated that they *had* abandoned its use, and that, *in cases suggestive of occlusive disease* of the aorta, surgical exposure and direct examination of the aorta and *its branches* was the optimal method of examination at this

time. Crawford et al. (1957) did not think aortography was necessary for diagnosis of complete obstruction of the abdominal aorta in those patients whose general condition prohibited surgery, but stated that it was of value in the diagnosis of incomplete obstruction and in the planning of surgery for this lesion Ellis and Kirklin (1956) stated that, although diagnosis usually could be made on the basis of clinical findings, aortography was an invaluable diagnostic aid in determining the site and extent of obstructions, delineating collateral circulation, and determining the patency of distal vessels.

Translumbar aortography, however, has been used in numerous cases (de Wolfe et al., 1954; Ellis and Kirklin, 1956) without mention of a serious reaction. Bahnson (1956) stated he used it in all of his cases but did not comment on complications. DeBakey (1958) stated that no complications had occurred in 300 cases examined since the precautions below, recommended by Crawford et al (1957), were followed.

1 Use aortography only when necessary.

2 Do not use it in complete aortic occlusion.

3. Limit the volume of injection to 15 to 25 ml of Urokon.

4. Use low concentration of the dye (70 per cent), and insert the needle below the renal arteries

According to Koszewski et al (1958), aortography is contraindicated in renal failure, and a blood urea-nitrogen content of 40 mg/100 ml is the limit above which aortography should not be attempted. It probably should not be done when there is a history of allergy. Koszewski et al. routinely administer *cortisone prior to examination.*

Occasionally, *femoral arteriograms* are also used to determine the extent of iliac thrombosis and the degree of arteriosclerosis of the major arteries in the legs. Rather than performing femoral arteriography, Ellis and Kirklin (1956) believe it is wise to explore the femoral arteries if aortograms fail to reveal patent vessels distal to the obstruction on delayed films and femoral pulsations are absent

Diagnosis. Despite the fact that diagnosis can usually be made on the basis of clinical findings alone, many patients are first seen by orthopedists or neurosurgeons. Because the syndrome of terminal insidious thrombosis of the aorta and iliac arteries is not widely known, the correct diagnosis often is not made, and a mistaken diagnosis is common.

Thrombosis of the aortic bifurcation should be suspected in patients complaining of easy fatigability of the legs, impotence, and pain in the lower back or abdomen, buttocks, hips, or thighs. The pain characteristically is brought on by exercise, especially walking, and relieved quickly by rest. Diagnosis is confirmed by absent or weak femoral pulsations. *A murmur may be heard over the groin when stenosis is present or collateral vessels are enlarged* Although aortography is not indispensable, many consider it important in confirming the diagnosis and determining the location and extent of the obstruction.

Massarelli and Estes (1957) stated that the diagnosis of aortoiliac occlusion was made clinically in 105 patients with intermittent claudication and bilaterally reduced or absent femoral pulses. This diagnosis was proved by aortography in eight cases and by necropsy in three.

Neither embolism nor acute thrombosis is usually mistaken for this syndrome. Most of the 47 patients reported by de Wolfe et al. (1954) were undiagnosed before admission; and many were referred as orthopedic problems with diagnoses such as ruptured intervertebral disks, osteoarthritis of the lumbosacral spine or hip, or bursitis of the hip. Differentiation is not difficult if one remembers to check the status of the arterial circulation of the legs of every patient who complains of pain in the lower back, hip, thigh, and leg Then, a carefully taken history will enable one to decide whether or not there *is true* intermittent claudication which can be caused only by reduced vascular supply to the musculature

Hypertrophic arthritis as a cause of hip pain is common after the age of fifty. The pain may be exaggerated by activity and relieved by rest, but the rest must be prolonged Some restriction of movement accompanies the pain, and roentgenograms may reveal typical cystic and sclerotic changes involving the acetabulum and the head of the femur.

Nonsuppurative bursitis or localized fibrosis are the most common causes of hip pain before the age of fifty. In bursitis, there is pronounced

tenderness over the bursa, and passive movements of the hip will usually aggravate the pain. In fibrosis, there are "trigger points" or areas of extreme tenderness in the muscle bellies or tendinous attachments of the muscles, and local infiltration of these tender areas with Novocain will usually give immediate relief.

Any pressure on, or irritation of, the fifth lumbar or first sacral nerve roots may cause pain in the posterior hip region and radiating down the course of the sciatic nerve. A protruding disk is not dependent upon movement for pain production, and the pain is almost always aggravated by bending, lifting, coughing, or straining. A protruded disk usually produces some change in the deep tendon reflexes of the involved extremity, and may cause characteristic sensory changes and muscular weakness in the leg.

Prognosis. Massarelli and Estes (1957) reviewed the natural history of 105 patients considered to have aortoiliac occlusion, the review covered survival rate, cause of death, development of ischemic changes in the lower extremities, severity of ischemic symptoms in surviving patients, and incidence of atherosclerosis elsewhere in the body

Survival rates for a period of 8 years after the time of diagnosis are somewhat less favorable than for those of a comparable normal population (Mayo Clinic). Thirty-six of the 105 patients were known to have died. Twenty-five (69.5 per cent) of these died as the direct result of atherosclerosis of the coronary or cerebral arteries. Five other patients presumably died as the result of atherosclerosis (two with congestive heart failure, one with rupture of a thoracic aneurysm, and two with generalized atherosclerosis). Thus, probably 30 of the 36 deaths were due to atherosclerosis elsewhere. None were known to have died from aortoiliac occlusion. Thirteen patients had some peripheral ischemic change other than claudication. Four had amputations as the result of peripheral atherosclerosis. Minor trophic changes of the toes occurred in three patients. Two diabetic patients had ulcers on their feet. Fifty-seven patients were followed for a minimum of two full years with respect to claudication. It was unchanged in severity from the time of diagnosis in 33, somewhat improved in 12, and increased in only 8.

The 3-year survival rate for patients with evidence of coronary or cerebral atherosclerosis, or both, at the time of diagnosis, was 60.0 per cent, as compared with 83.1 per cent for patients without such evidence. Although occlusion of one or both renal arteries has been reported elsewhere, renal-artery occlusion did not occur in the 105 patients reviewed.

During a 6-year study of 65 cases by Beckwith et al. (1958), 22 patients died while under observation. The duration of life from the onset of symptoms varied from 1 to 20 years, with a mean duration of 6 to 7 years. Death was usually due to disease of the coronary, renal, or cerebral arteries. The aortic thrombus extended cephalad to involve the renal arteries in only two cases.

Aortoiliac resection and grafting has an operative mortality rate of 4 to 5 per cent, and may relieve the high-level claudication, but obviously will have no effect on the cerebral, coronary, or peripheral atherosclerosis.

Treatment. Sufficient data are not available for adequate comparison of patients treated by resection and graft replacement and those treated conservatively.

Conservative treatment consists of bilateral lumbar sympathectomy, reflex heat to the abdomen for 20 min or more daily, elevation of the head of the bed 4 to 6 in., and instruction concerning the care of the feet. Smoking is forbidden.

Most authors now consider sympathectomy inadequate, however, Grimson et al. (1955) stated that excision of the lower thoracic and all of the lumbar ganglia gave encouraging results in the treatment of 19 patients who had unilateral or bilateral obstruction of the iliac arteries and the terminal aorta and viable limbs. There was no operative mortality, and only one limb required amputation—4 years after sympathectomy. These authors stated that results of this procedure were evaluated best by the satisfaction of the patient and warmth of the limb, and poorest by relief from claudication or improvement in oscillometric readings.

Leriche (1923) suggested that the ideal treatment would be resection of the occluded aortic segment with suture closure of the divided ends, and was the first to perform a terminal aortectomy together with a bilateral ganglionectomy (Leriche, 1940). Later Leriche and Morel (1948) emphasized the use of high bilateral lumbar ganglionectomy with resection of the thrombosed segment.

Thromboendarterectomy for aortic or iliac

obstruction was first reported by dos Santos (1947). Because *thrombosis tends to recur*, this operation has been discarded by *most* surgeons, although some *consider it satisfactory* for patients with a *short area of obstruction*.

At present, *excision of the involved area* and *grafting* are generally considered the procedures of choice. *The procedure is relatively simple, and good results can be expected if* distal vessels *are patent. If the* vessels are not patent distally, *the chances of getting into difficulty* with impaired circulation to the leg after operation are *considerable*.

Dubost et al. (1952) were the first to *resect a* portion of the abdominal aorta and use a *graft replacement*, but this was for an aortic *aneurysm*. *DeBakey et al (1955c)* reported their experiences *with 68* patients who had thromboobliterative *disease of the* abdominal aorta, in 64 of these excision of *the terminal* aorta and bifurcation together with *replacement* by *homograft were* performed There were only two *operative deaths* Three patients died later: one from *heart failure*, one from septicemia, and one from *hemorrhage* caused by rupture of the iliac artery *at the line* of anastomosis. All but four of the remaining 63 *patients* showed definite improvement Follow-*up studies* extending *2 to 5 years* revealed *maintenance of the good immediate* postoperative results. Bahnson *(1956) reported* good results on 14 and fair results on *patients on* whom excision and aortic reconstruction with *homografts* were performed. Ellis and Kirklin *(1956)* reported *two deaths*, a mortality rate of 4 per cent, in a group *of 47* patients undergoing resection and *grafting* for occlusion of the aorta or iliac arteries *or both* Forty patients (85 *per cent*) were improved, and the authors considered *these* results *eminently* satisfactory

Beckwith et al. (1958) reported a *series of eight* selected patients who underwent *resection and* homograft replacement There was one *hospital* death, and seven patients were distinctly *benefited* Patients considered suitable were *those with* minimal atherosclerotic involvement *elsewhere*, including the distal vessels, however, suitable patients were rare because of the usual *associated* generalized atherosclerosis.

Massarelli and Estes (1957) described the "ideal" candidate for surgery, recognizing that the primary aim was relief of claudication. *The* candidate should have "*sufficiently severe* claudication" to warrant both the *mortality* and morbidity risk and the expense and inconvenience of surgical treatment. Preferably, the *candidate should* have no clinical evidence of *coronary* or cerebral atherosclerosis, no diabetes mellitus, and no other significant systemic disease. Then, if the femoral arteries are patent, he may be considered an ideal candidate for aortic resection and graft.

At present, experience with *synthetic aortic substitutes* is encouraging, but the durability of these materials under biologic conditions has not yet been fully determined The most satisfactory materials to date appear to be Dacron *and Teflon.* DeBakey (1958) is now using Dacron exclusively for all grafts.

EMBOLISM

Causative Factors. Over 90 *per* cent of the cases of systemic arterial embolism arise from thrombi in the left atrium or ventricle.

Haimovici (1950) reviewed 230 unselected cases of peripheral arterial embolism and found *that* 51 per cent were associated with *coronary heart disease* and that 44.4 per cent were associated with *rheumatic heart disease.* Flasher and Stephenson (1952) reviewed 212 cases and found 145 cases (69 per cent) to be of atrial origin, and only 50 (23 per cent) to be of ventricular origin.

Although bacterial endocarditis causes about 5 per cent of systemic arterial emboli, they are of no significance in embolism of the aortic bifurcation because of their small size. Other, rarer, causes are paradoxical emboli from systemic veins or the right side of the heart and emboli from thrombi in the pulmonary veins *or* in aortic aneurysms.

In rheumatic heart disease, most left atrial thrombi occur in cases with *predominant mitral stenosis* They occur less frequently when regurgitation is superimposed upon stenosis, and still less frequently when regurgitation is present alone (Storer et al, 1954). However, *atrial fibrillation* is the main correlate regardless of the mitral lesion (Askey, 1957). Harvey and Levine (1930), after reviewing 111 cases of uninfected atrial thrombosis, concluded that atrial fibrillation undoubtedly increased the incidence of atrial thrombosis. Prinzmetal et al. (1952) stated that it was not the fibrillation itself but the concurrent stasis caused by mitral obstruction that predisposed to the thrombosis. Atrial fibrillation occurs not only at a later age but also later in the course of mitral *disease. It* occurs more frequently in pure mitral regurgitation than in pure *mitral stenosis* (Storer

et al., 1954; Janton et al., 1954) and indicates prolonged stasis in cases of pure stenosis with minimal but moderate regurgitation, and prolonged but minimal stasis in cases of pure regurgitation

Increased blood coagulability may contribute to thrombosis in the older patients.

By compiling data from 450 cases of rheumatic heart disease with clinically recognizable systemic arterial embolism (presumptive evidence of left atrial thrombosis), Askey (1957) found that emboli were most frequent in patients *without* congestive failure, indicating that thrombi usually form *before* the onset of congestive failure. Daley et al. (1951) were unable to correlate the duration and severity of failure with systemic arterial emboli. Enlargement of the mitral orifice by commissurotomy is occasionally followed by an embolus large enough to obstruct the aortic bifurcation

In left ventricular (*mural*) *thrombosis*, the thrombotic tendency of the *endothelium* with damage secondary to myocardial *infarction* is much greater than in rheumatic fever. This strong thrombotic tendency is exaggerated by stasis, which is increased by congestive heart failure The greater incidence of thrombi in infarcts of the anterior wall is probably caused by increased stasis at the apex, especially in congestive failure (Jordon et al, 1952) The incidence of thrombi is less in healed *infarctions*

Thus, prolonged *stasis* is needed for thrombus formation in the left atrium. In atrial thrombosis, atrial fibrillation is an important correlate while heart failure is not. Endothelial damage is the most important factor in thrombosis of the left ventricle Here, atrial fibrillation is not a correlate, but heart failure definitely is.

Daley et al (1951) analyzed 393 cases of systemic arterial embolism and found that 23 (5 9 per cent) had lodged *at the bifurcation of the aorta* Haimovici (1950) stated that, in 330 cases of arterial embolism, 9 1 per cent had lodged there

In general, the factors which tend to dislodge thrombi from cardiac cavities are also those which tend to prevent their formation In most instances, however, there is no satisfactory explanation for the mobilization of left atrial thrombi, although occasionally there appears to be a definite relation to a sudden change in cardiac rhythm (Askey, 1957) Of special significance in aortic embolism is the fact that the mitral orifice must be small enough to cause the necessary stasis for clot formation, but sufficiently large to permit the passage of an embolus large enough to obstruct the aortic lumen. A change in the contractions of the ventricular wall probably is the most important factor in the dislodgment of left ventricular mural thrombi.

When the emboli become lodged, a local reaction of *edema* starts in the intima, and the force of blood behind the embolus increases the pressure on the intimal wall accelerating the reaction (Pratt, 1954). *Arterial spasm* probably always occurs, affecting the collateral circulation as well as the involved vessels. Hesse (1921) stated that vasospasm occurred in 97 per cent of the cases of saddle embolism, especially distally. In fact, total occlusion of the lumen by the embolus is not essential Partial block may be converted to complete block by vasospasm and subsequent secondary thrombosis (Reich, 1949). In more than *one-half* of the patients, a soft clot is propagated distally

Symptoms. The most dramatic clinical picture of sudden arterial occlusion occurs when *the abdominal aorta is occluded at its bifurcation* (*saddle embolus*) (Allen et al, 1955).

There is usually a history or symptoms of heart disease

The presenting symptom is usually *leg pain,* although it may be minor or absent in 15 to 20 per cent (Pratt, 1954) *Abdominal or sacral pain* may predominate. Of 27 cases, lower abdominal or sacral pain was recorded in 15 (Taylor, 1951).

Pain often decreases as other symptoms such as *paresthesia, anesthesia,* and *paralysis* become more marked. Occasionally, paresthesia and anesthesia overshadow pain. Paresthesia or anesthesia was recorded in 23 of Taylor's 27 cases, and paralysis of the lower extremities was present in more than one-half of the patients

Signs. Most of the patients with embolism of the aortic bifurcation appear *anxious* Signs of heart disease are often evident *Coldness of the skin, pallor,* or *cyanosis* are present. In more than one-half of Taylor's cases the skin of the legs was mottled, and in the rest the skin was recorded as being cyanotic or white. The marble-white appearance described in aortic thrombosis is not characteristic of embolic aortic occlusion. The appearance of the

skin seems to depend largely upon the amount of venous stasis or collateral blood supply, and is of no diagnostic value.

Anesthesia of the feet is complete. Paralysis involves the small muscles of the feet, and usually includes motor muscle groups to the ankle (Pratt, 1954).

Complete absence of pulsation of the femoral, popliteal, and more distal pulses is almost constant; occasionally, however, it is only diminished, the lessened pulsation being produced by pounding of the blood pressure against the occlusion or by transmission of the pulse through the fluid in the iliac system. Absence of pulsation of the aorta over the sacral promontory together with normal pulsations more craniad have been described.

Technical Study. Because of the importance of elucidating the source of the embolus, which arises from the left side of the heart in well over 90 per cent of the cases, roentgenographic and electrocardiographic studies of the heart are important

Roentgenography is most important in diagnosis of left atrial enlargement in mitral disease Sosman (1943) stated that fluoroscopy with optimal accommodation of the eyes is better than the roentgenogram in the diagnosis of calcification of the mitral valve, which he considers diagnostic if observed roentgenographically, regardless of the presence or absence of other signs.

Occasionally, the electrocardiogram is helpful The presence of notched P waves and a history of rheumatic fever suggest the probability of mitral stenosis. The electrocardiogram is, of course, the most valuable technical aid in the diagnosis of arteriosclerotic heart disease

Oscillometry is of limited value since the same information can be obtained by careful digital examination.

Diagnosis. The six "P's" of arterial occlusion which may aid in diagnosis are pain, paralysis, paleness, pulselessness, paresthesia, and prostration. The following triad may also be helpful in diagnosis· (1) sudden complete loss of pulse to the lower extremities with resulting ischemia; (2) presence of a heart lesion capable of casting off an embolus large enough to occlude the terminal aorta, (3) absence of history suggesting aortic thrombosis on an arteriosclerotic basis.

Signs and symptoms of sudden occlusion of the aortic bifurcation should cause one to suspect and look for heart disease, either coronary or rheumatic with mitral stenosis. When such signs or symptoms suddenly occur in patients with rheumatic or coronary heart disease, one should suspect aortic embolism. This is particularly true if mitral stenosis is accompanied by atrial fibrillation, or if coronary heart disease with myocardial infarction is accompanied by heart failure.

It is well to remember, however, that the onset of symptoms in embolic obstruction of the aortic bifurcation may not be sudden, that occasionally the episode may be silent, and that numbness or coldness may be the initial symptoms instead of pain.

Acute aortic thrombosis and acute phlebothrombosis with massive arterial spasm are the main differential diagnostic problems A primary point is the presence or absence of a source for emboli, particularly rheumatic mitral disease or coronary heart disease.

Although the onset of thrombosis at or near the bifurcation of the aorta is usually gradual, it may be sudden. If thrombosis is superimposed upon a high degree of stenosis which has developed slowly, the collateral circulation lessens the severity of the symptoms, and often there is a history of failing circulation in the legs. If thrombosis develops on an ulcerated atherosclerotic plaque and the aortic lumen is almost normal, peripheral symptoms and signs may be similar to those of an embolism at the aortic bifurcation. Heart disease does not necessarily accompany acute thrombosis

In thrombophlebitis with massive spasm of the corresponding artery, the symptoms and signs are unilateral. Initially, edema and cyanosis may be absent, and the corresponding femoral pulse may be temporarily absent After a few minutes to a few hours, edema and cyanosis appear, and the femoral pulse returns In phlebothrombosis, the leg is generally warmer than in embolism Paralysis and other differential points of embolism are important. If necessary, paravertebral blocks and antispasmodic drugs may help differentiate vasospasm.

Warren and Linton (1948) suggest that it is better to err on the side of embolism because therapy cannot wait upon academic proof

Concurrent venous thrombosis may occasion-

ally accompany embolism, and often occurs in cases terminating unfavorably.

Prognosis. The natural clinical course depends upon the degree of development of collateral circulation, the cardiac *status, and* the general condition of the patient. *Death or loss of limb occurs in a large proportion of patients with aortic embolism. When there is no surgical intervention, practically all patients die.* Successful *embolectomy* offers the only prophylaxis against impending gangrene, but does not alter the cardiac hazard. Successfully embolectomized patients may subsequently die of the severe cardiac disease which is the source of *the large aortic* embolus or of a subsequent fatal embolism. Because of this, the mortality rate is nearly as great with embolectomy as without it (Pratt, 1954, Dye et al., 1955)

In an analysis of 128 untreated or conservatively treated cases, Haimovici (1950) reported that 61 (47.6 per cent) died in the hospital. Of 67 patients discharged alive, 56 (43.8 per cent) had no follow-up, 6 (4.7 per cent) died in 6 to 24 months, and 5 (3.7 per cent) were alive with a follow-up of 2 to 10 years. The hospital mortality rate of surgically treated cases was 51.7 per cent which was slightly above that of the medically treated cases.

Reviewing his total series of 300 cases, Haimovici found that the proportion of marked ischemia and early deaths was about the same in patients not treated, in those treated late or poorly (heat on or elevation of extremities), and in those treated properly and early (*within 12 hr*), *and* varied from 11.3 per cent in the first group to 14.4 per cent in the last. Late or poor treatment *increased the incidence of gangrene from 28* per cent in the untreated cases to 35.3 per cent, early and proper conservative treatment decreased the *incidence of gangrene* to 14.4 per cent. Poor or late treatment increased the incidence of chronic postembolic ischemia, and decreased the incidence of nonischemic limbs.

Most authors agree that survival of the limbs is greater, and that gangrene and ischemic pain of the extremities are less, when *embolectomy* is performed. Favorable local results depend upon early treatment, the condition of the endothelium following surgery, and the state of the distal arteries before embolectomy. Embolectomies have been more frequently successful since the advent of *anticoagulants*.

In rheumatic heart disease, the danger of future embolism is statistically much greater after the first attack. Once a thrombus is formed in the left atrium and has been mobilized, the underlying background for recurrent embolism persists and, until this is altered, the frequency of recurrent emboli will remain unchanged.

In a series of 60 "successful cases" following embolectomies of all types, one-fourth died from recurrent embolism within 1 year, one-half in 3 years, and two-thirds in 5 years. *Hemiplegia* occurred in 12 of the 41 patients who died and in 4 of the 19 survivors (Strombeck, 1935). *About* half of the rheumatic fever patients who recovered from a first embolus of any type eventually died of recurrent arterial embolism (Askey, 1957). Of 201 *recurrent* episodes of embolism in rheumatic heart disease, 144 (71 per cent) *occurred* within the first year. Of these, as many occurred within the first month as within the last 11 months, and of these, as many occurred in the first week as within the next 3 weeks (Daley et al., 1951).

Prognosis, especially in the rheumatic fever group, has strikingly improved since the advent of anticoagulants and cardiac surgery. Wright and Foley (1947) first showed that recurrent embolism in rheumatic heart disease could be reduced by continuous *Dicumarol* therapy. Summarizing five reports on 98 patients followed for 1,944 months without Dicumarol before the first recognizable embolism, and for 2,995 months with Dicumarol after embolism, Askey found that the incidence of embolisms was reduced from 1 in 7 months to 1 in 7 years.

The occurrence of emboli after mitral valvuloplasty is almost nil. Glover et al (1954) stated that, in a postoperative experience covering 6 years, only one questionable and minor embolic episode occurred in 700 patients. Bland et al (1954) reported that only one possible small cerebral embolism occurred during 70 months following valvuloplasty performed on seven patients who had had 30 embolisms in 372 months preceding surgery. Crane (1958) reported results of embolectomy on 14 patients, 12 with mitral stenosis and 2 with recent myocardial *infarction*. Ten of the twelve rheumatic patients survived. Eight of the ten did well, and two required low-thigh amputation. Mitral valve *surgery* was performed on eight of the ten living *patients, four* shortly before embolectomy and four afterwards.

skin seems to depend largely upon the amount of venous stasis or collateral blood supply, and is of no diagnostic value.

Anesthesia of the feet is complete. Paralysis involves the small muscles of the feet, and usually includes motor muscle groups to the ankle (Pratt, 1954).

Complete absence of pulsation of the femoral, popliteal, and more distal pulses is almost constant; occasionally, however, it is only diminished, the lessened pulsation being produced by pounding of the blood pressure against the occlusion or by transmission of the pulse through the fluid in the iliac system. Absence of pulsation of the aorta over the sacral promontory together with normal pulsations more craniad have been described.

Technical Study. Because of the importance of elucidating the source of the embolus, which arises from the left side of the heart in well over 90 per cent of the cases, roentgenographic and electrocardiographic studies of the heart are important

Roentgenography is most important in diagnosis of left atrial enlargement in mitral disease Sosman (1943) stated that fluoroscopy with optimal accommodation of the eyes is better than the roentgenogram in the diagnosis of calcification of the mitral valve, which he considers diagnostic if observed roentgenographically, regardless of the presence or absence of other signs

Occasionally, the electrocardiogram is helpful. The presence of notched P waves and a history of rheumatic fever suggest the probability of mitral stenosis The electrocardiogram is, of course, the most valuable technical aid in the diagnosis of arteriosclerotic heart disease.

Oscillometry is of limited value since the same information can be obtained by careful digital examination.

Diagnosis. The six "P's" of arterial occlusion which may aid in diagnosis are pain, paralysis, paleness, pulselessness, paresthesia, and prostration. The following triad may also be helpful in diagnosis: (1) sudden complete loss of pulse to the lower extremities with resulting ischemia; (2) presence of a heart lesion capable of casting off an embolus large enough to occlude the terminal aorta; (3) absence of history suggesting aortic thrombosis on an arteriosclerotic basis.

Signs and symptoms of sudden occlusion of the aortic bifurcation should cause one to suspect and look for heart disease, either coronary or rheumatic with mitral stenosis When such signs or symptoms suddenly occur in patients with rheumatic or coronary heart disease, one should suspect aortic embolism. This is particularly true if mitral stenosis is accompanied by atrial fibrillation, or if coronary heart disease with myocardial infarction is accompanied by heart failure.

It is well to remember, however, that the onset of symptoms in embolic obstruction of the aortic bifurcation may not be sudden, that occasionally the episode may be silent, and that numbness or coldness may be the initial symptoms instead of pain.

Acute aortic thrombosis and acute phlebothrombosis with massive arterial spasm are the main differential diagnostic problems A primary point is the presence or absence of a source for emboli, particularly rheumatic mitral disease or coronary heart disease.

Although the onset of thrombosis at or near the bifurcation of the aorta is usually gradual, it may be sudden. If thrombosis is superimposed upon a high degree of stenosis which has developed slowly, the collateral circulation lessens the severity of the symptoms, and often there is a history of failing circulation in the legs. If thrombosis develops on an ulcerated atherosclerotic plaque and the aortic lumen is almost normal, peripheral symptoms and signs may be similar to those of an embolism at the aortic bifurcation. Heart disease does not necessarily accompany acute thrombosis

In thrombophlebitis with massive spasm of the corresponding artery, the symptoms and signs are unilateral Initially, edema and cyanosis may be absent, and the corresponding femoral pulse may be temporarily absent. After a few minutes to a few hours, edema and cyanosis appear, and the femoral pulse returns. In phlebothrombosis, the leg is generally warmer than in embolism. Paralysis and other differential points of embolism are important. If necessary, paravertebral blocks and antispasmodic drugs may help differentiate vasospasm.

Warren and Linton (1948) suggest that it is better to err on the side of embolism because therapy cannot wait upon academic proof.

Concurrent venous thrombosis may occasion-

but it is desirable to intervene earlier if possible.

Labey (1911) performed the first successful embolectomy, but Bauer (1913), using a midline transperitoneal exposure, is given credit for the first successful removal of an aortic embolus. Nystrom (1936) developed the "retroperitoneal Hinuntermelkung" procedure which consisted of introducing one hand beneath the inguinal ligament and behind the peritoneum until the embolus could be outlined by palpation The embolus then was milked downward by the exploring fingers until it could be removed through an iliac or femoral artery incision.

Murray (1943) reported the first group of successful cases of aortic embolectomy, however, isolated successful cases had been previously reported Warren et al (1954) reported a series of 17 cases, of which seven survived with preservation of both limbs, and one with one limb

At present, most authors prefer to use the direct exposure of the bifurcation of the aorta, either by the transperitoneal or the extraperitoneal approach

Most authors consider *heparin* administration important in the preoperative and postoperative periods Crane (1958) states that the decision whether or not to use heparin postoperatively should be weighed in each case. Heparinization may cause major blood loss after retroperitoneal dissection Therefore, if it is used, hematocrit determinations should be made twice daily.

In seriously ill patients, aspiration of the embolus from below the inguinal ligament through the common femoral artery on both sides may be attempted under local anesthesia. If this fails, the direct approach is necessary.

If patients are eligible for mitral valvuloplasty, this procedure should be considered before embolectomy or as soon as practical thereafter. *Mitral valvuloplasty* should be considered immediately after any arterial embolism because minor attacks often precede major ones Glenn and McNeill (1957) performed a successful emergency valvuloplasty before embolectomy in a patient who had hypotension and pulmonary edema and who did not respond to usual therapeutic measures They stated that, when signs of severe congestive heart failure are present, it appears reasonable to consider an *emergency valvulotomy and atrial appendectomy* before aortic embolectomy. In Crane's series (1958), four valvuloplasties were performed successfully before embolectomy, and four were performed successfully afterwards

The striking recent improvement in prognosis in the rheumatic group is presented well in the statements of two observers over the period of the last 7 years. In 1951, Taylor stated that "successful aortic embolectomy is so spectacular as to completely overshadow its true medical worth. It is fortunate that this procedure does not have to be considered in the light of its general medical benefit. Mankind would be far better served if the same time, effort, and money would be spent on some dull public health problem." In 1958, Crane stated that "with improved preoperative medical management of cardiac patients, greatly improved anesthetic techniques, monitoring of the heart during operation, the widespread betterment of vascular surgery in general, and the prevention of further emboli by cardiac surgery, the patient sustaining aortic embolism has a good outlook, provided diagnosis is prompt and early embolectomy done."

That recurrent embolism is a sequela of myocardial infarction is well known, but the incidence is less well established than in rheumatic heart disease. Although the outlook is grave in patients with aortic embolism and coronary heart disease with myocardial infarction, the consensus is that the incidence of thromboembolism is significantly reduced by the practice of continuous anticoagulant therapy.

Treatment. Prophylactic treatment primarily consists of (1) *anticoagulant therapy* in rheumatic heart disease with mitral stenosis after an initial embolism, in coronary heart disease after myocardial infarction, and in congestive failure (providing no contraindication exists); and (2) mitral valvuloplasty in eligible patients with mitral stenosis.

A most important step is the recognition of a minor embolism which usually precedes a large or fatal one.

Continuous anticoagulant therapy is indicated in eligible patients with mitral stenosis who are ineligible for or refuse valvuloplasty. Although any reduction in prothrombin activity reduces the incidence of thromboembolism to some extent, moderate reduction is sufficient for many patients. Askey (1957), after treating 304 patients with chronic cardiovascular disease for periods of 3 months to 9 years, concluded that 50 per cent reduction in prothrombin activity was satisfactory in ambulatory patients. The patient, of course, should be properly instructed concerning precautions and complications.

Contraindications to prolonged anticoagulant therapy are conditions which predispose to serious hemorrhage, inadequate laboratory facilities, inexperience of the physician, and the inability of the patient to cooperate for one reason or another.

Patients who are eligible for *mitral valvuloplasty* should, of course, be operated upon, and anticoagulant therapy should be maintained until surgery and, possibly, through surgery. Storm and Hansen (1955) maintained Dicumarol therapy through mitral valvuloplasty in 26 cases and found no more hemorrhage than they did in 26 control cases. None of the treated cases had thromboembolic complications, but four of the control cases had postoperative cerebral embolisms. It is important to check peripheral pulses before and after surgery because of the relative frequency of postoperative emboli.

Treatment of embolism of the aortic bifurcation may be conservative or surgical.

Conservative measures include anticoagulants, protective bandages for the limb, reflex hyperemia, vasodilator drugs, and paravertebral sympathetic block. Elevation of the extremities increases the ischemia, and the application of heat increases tissue metabolism, so they should not be used. Cooling slows down tissue metabolism, but increases vasospasm, and is not recommended.

Embolectomy is the method of choice and should be considered in every case, especially if conservative measures fail after 2 to 4 hr. Crane (1958) stated that embolectomy should be done as soon as practical for five reasons: "Signs of improvement in circulation are often transient, and valuable time is lost in wishful thinking, no one can tell with certainty whether or not an embarrassed limb will survive because of the constant hazard of added thrombosis in the blocked arterial tree; anticoagulant therapy is only partially effective in preventing clot propagation; no collateral flow can truly replace main channel flow; and late thrombectomy or thrombendarterectomy is more difficult to accomplish and much less rewarding than early embolectomy." *Complete restoration of the arterial lumen usually can be accomplished if embolectomy is performed within 6 to 10 hr,*

but it is desirable to intervene earlier if possible.

Labey (1911) performed the first successful embolectomy, but Bauer (1913), using a midline transperitoneal exposure, is given credit for the first successful removal of an aortic embolus Nystrom (1936) developed the "retroperitoneal Hinuntermelkung" procedure which consisted of introducing one hand beneath the inguinal ligament [illegible]

til it could be removed through an iliac or femoral artery incision.

Murray (1943) reported the first group of successful cases of aortic embolectomy; however, isolated successful cases had been previously reported Warren et al (1954) reported a series of 17 cases, of which seven survived with preservation of both limbs, and one with one limb

At present, most authors prefer to use the direct exposure of the bifurcation of the aorta, either by the transperitoneal or the extraperitoneal approach

Most authors consider *heparin administration* important in the preoperative and *postoperative* periods Crane (1958) states that the decision whether or not to use *heparin postoperatively* should be weighed in each case Heparinization may cause major blood loss after retroperitoneal dissection. Therefore, if it is used, hematocrit determinations should be made twice daily.

In seriously ill patients, aspiration of the embolus from below the inguinal ligament through the common femoral artery on both sides may be attempted under local anesthesia If this fails, the direct approach is necessary.

If patients are eligible for mitral valvuloplasty, this procedure should be considered before embolectomy or as soon as practical thereafter. *Mitral valvuloplasty* should be considered immediately after any arterial embolism because minor attacks often precede major ones. Glenn and McNeill (1957) performed a *successful emergency* valvuloplasty before embolectomy in a patient who had hypotension and pulmonary edema and who did not respond to usual therapeutic measures. They *stated that*, when signs of severe congestive heart failure are present, it appears reasonable to consider an *emergency valvulotomy and atrial appendectomy* before aortic embolectomy In Crane's series (1958), four valvuloplasties were performed successfully before embolectomy, and four were performed successfully *afterwards*

Dissecting and mycotic aneurysms of the aorta

Pathological Aspects

PATHOLOGICAL ASPECTS

DISSECTING ANEURYSMS

Dissecting aneurysm is the designation given to the vascular deformity which results from hemorrhage within the wall of an artery For practical purposes, it is a condition confined to the aorta; involvement of other channels rarely occurs Historically, Laënnec (1826) introduced the diagnostic term, however. Shennan has credited Nicholls (1761) with the first unmistakable description A century later (1863) Peacock was able to assemble 80 cases for review The clinical diagnosis of dissecting aneurysm dates from the case of Swaine and Latham (1856) As late as 1934, Shennan was able to find only six cases that had been recognized clinically, but since then, ante-mortem diagnosis has become commonplace

TABLE 15-1 EFFECT OF REENTRY ON THE PERIOD OF SURVIVAL

	Reentry	*No reentry*

Less than 5 weeks	26 (28%)	192 (96%)
More than 5 weeks	66 (72%)	7 (4%)
Total	92	199

SOURCE: Morgan-Jones and Langley, 1946

There is evidence of an increasing frequency of aortic dissection and currently it comprises 12 to 25 per cent of all aortic aneurysms The incidence is greatest between the ages of 40 and 60 years, though no age group is exempt Men are twice as often affected as women, but this difference lessens after the age of sixty. Negroes seem more susceptible than Caucasians but by allowing for the greater frequency of hypertension among Negroes, Levinson et al. found no difference in the incidence of dissecting aneurysm

Dissecting aneurysm carries a very high mortality; most victims succumb within a short time but sudden deaths are uncommon. According to Hirst et al , 79 per cent live longer than 24 hr, 51 per cent more than 4 days, and 26 per cent longer than 2 weeks. DeBakey et al (1955b) have emphasized that prompt clinical diagnosis allows adequate time for surgical intervention In a minority of cases, survival may be prolonged. Sixteen of 300 cases collected by Shennan lived longer than 1 year, Morgan-Jones and Langley (1946) described an instance of 30-year survival External rupture of the aneurysm and hemorrhage causes death in the great majority of acute cases Bleeding occurs into the pericardium in 75 per cent of cases; other sites in order of frequency are the pleural cavities, the medi-

astinum, and the retroperitoneal space. Internal rupture or reentry improves the possibility of prolonged survival by reducing the incidence of hemorrhage. The prognosis is also improved as the distance of the intimal tear from the aortic ring increases

Congestive heart failure and hemorrhage are the principal causes of death in chronic dissecting aneurysm. Hemorrhage results from rupture of the original lesion or from additional and even multiple independent episodes of dissection

Pathological Findings. Most of the gross features of dissecting aneurysm have been known for more than 100 years Elliotson observed in 1829 that the ascending aorta was the usual site of the lesion and that internal rupture (when present) was commonly transversely oriented. Independently, Pennock (1838) and Henderson (1843) recognized that dissection occurred within the media, Henderson even localized it more precisely to *the outer portion* of that layer. As shown in Table 15-2, the initial intimal tear may involve other portions of the aorta.

The external deformity of the aorta results from the intramural hemorrhage and may be *saccular* or *fusiform* Often the natural lumen is narrowed by the inward bulge of the false channel. The longitudinal extent of dissection varies from a few millimeters, so-called "spontaneous rupture," to the length of the aorta, even more when it extends beyond the bifurcation (Figs 15-7 and 15-8). Cleavage usually extends distally but some degree of *retrograde* extension is common, particularly with prolonged survival. Seventy-six per cent of dissections originate *in the ascending aorta* Of this 76, 36 do not progress further than the arch and 40 extend into the thoracic and the abdominal aortas Sixteen per cent of dissecting aneurysms arise in the aortic arch and most of them progress to involve the abdominal aorta. Even more distal dissection is not uncommon; Gore and Seiwert found the vessels to the lower extremities to be involved in 19 of 85 cases Despite the involvement of the abdominal aorta in more than half of all dissections, the terminal hemorrhage is intrathoracic in the great majority. Even patients with older, canalized dissecting aneurysms frequently succumb to hem...

Abdominal aorta	2

Reference has already been made to the importance of reentry tears in favoring survival; however, absence of such a second tear does not preclude prolonged survival. As it progresses within the wall of the aorta, the dissecting hemorrhage may compress or intercept subsidiary channels. Almost invariably some of the numerous segmental arteries are involved (Fig. 15-7). These, it will be recalled, are the source of the spinal arteries; their attenuation before tearing seems to account for *transient* cord symptoms. Depending upon pressure relations, the ostiums of the intercepted channels may provide a route for reentry into the aorta, moreover, the distal extensions of these arteries now arise from the false channel and also serve to decompress it The longitudinal and circumferential extents of medial cleavage are variable but the process may affect the coronary arteries, the great vessels of the arch, the celiac axis, the superior and inferior mesenteric, or the renal arteries. Of the 22 cases cited by Burchell, ". . . the right and left coronary orifices were each involved twice, the innominate artery five times, the left carotid six times, the left subclavian eight times, the celiac axis and superior mesenteric each twice, the left renal artery nine times and the right twice, and the left iliac 12 times and the right nine times" Rarely, the medial hemorrhage may extend into and along the great vessels of the arch just as it does, more frequently, into the iliac arteries.

Much has been made of the transverse orientation so frequently observed in the primary intimal tear, it has been considered a clue to the mechanical factors involved in the develop-ment of ...

...sons under 40 years of age. For this reason, *mechanical influences must be regarded as only supplementary to more fundamental structural changes.* With chronicity, the intimal opening becomes endothelialized and

Fig. 15-7. Heart and aorta Dissecting aneurysm. The arrow indicates the intimal tear in the supravalvular segment of the aorta. In the thoracic aorta at the top of the photograph are the ostiums of the disrupted segmental vessels

rounded or ovoid, and simultaneously an endothelium forms in the false channel Prolonged survival even permits the development of appreciable atherosclerosis in the newly formed intima

Occasionally dissecting aneurysms occur *without* an intimal tear, this type was described by Krukenberg (1920) and Tyson (1931). Six of the 85 cases studied by Gore and Seiwert were of this variety The survey of Hirst et al. led them to conclude that similar instances comprise about 10 per cent of all dissecting aneurysms. However, their relative infrequency is no measure of their significance since they

Fig. 15-8. Dissecting aneurysm of the aorta, transection magnified about 2½ times The false channel at the top is occupied by a thrombus which compresses and narrows the natural lumen. At the right side of the photograph, it is apparent that the cleavage plane involves the outer portion of the media The aortic intima is eccentrically thickened by degenerating and hemorrhagic atheromatous plaques which have only a coincidental relation to the medial dissection.

demonstrate that *intimal tearing is not the primary event* in the genesis of intramural dissection

An even more uncommon lesion, which should be grouped with dissecting aneurysms, is the one known as *incomplete rupture of the aorta*. This lesion, well-illustrated by Peery (1942) and by Fisher and Salmons (1950), had been originally described by Eppinger (1887) as a healed rupture. As the name implies, there is a gaping, nonpenetrating rent in the intima and media which characteristically lies in the supravalvular segment of the aorta. Usually the tear is transversely oriented and may be bridged by a few tenuous strands. Survival allows endothelialization of the base of the tear and reinforcement of the aortic wall by adventitial scarring However, the prognosis should be guarded since there is invariably medial degeneration and the probability of subsequent intramural dissection and pericardial hemorrhage There is also the additional hazard of aortic insufficiency resulting from the proximity of the lesion to the valve ring

Pathogenetic Factors. The frequency of hypertension coincident with dissecting aneurysm is such that it has been regarded by some as the principal pathogenetic factor However, since the lesion appears in normotensive persons, particularly in the younger age groups, elevated blood pressure cannot be more than a secondary factor. Nor do transitory increases of arterial pressure appear important; trauma, state of activity, or exertion have no demonstrable relation to the onset of dissection

The normal aorta resists bursting or dissecting pressures far in excess of those observed in the most extreme [illegible] in [illegible] is [illegible] of serious weakening of the vessel wall Although earlier students had considered intimal disease to be the weakening process, the site of origin of most dissections is in the proximal aorta, the portion least affected by atherosclerosis It is true that intimal disease is well advanced in the older age groups in whom dissecting aneurysm is most frequent, but the lesion occurs in young individuals in the absence of appreciable atherosclerosis. Moreover, coincidence of a plaque and an intimal tear is uncommon. Gore and Seiwert noted it only twice in 85 cases and Shennan only six times in 218 cases. But while intimal disease is not an explanation for dissecting aneurysms, *structural weakening of the media* is, and this has been observed to such a degree that mere manipulation may demonstrate the defect. Microscopically, the distribution and frequency of medial lesions in the aortic wall correspond to the distribution of intimal tears in dissecting aneurysm They occur uniformly in young as well as in aged victims of the disease. Although the major structural weakenings may have been destroyed by the intramural hemorrhage, it is possible to find focal degenerative medial lesions in virtually all cases.

Microscopically the medial changes are of two varieties The first, described by Gsell (1928), is characterized by foci of medial-muscle depletion with no alteration in the elastic laminas except condensation. Cellina observed similar lesions in senescence. Intercellular accumulations of mucoid material occur, but are not as prominent as in the second type of medial degeneration, described by Erdheim In the latter form there are large gaps and faults in the elastic laminas, these are filled with excessive accumulations of mucoid ground substance; these compress and distort the surrounding medial tissues With depletion of the elastic lamina the muscle fibers, which insert upon them, retract and become malaligned, but are otherwise unaltered. In a series of 72 cases reviewed histologically, 36 presented damage to the muscular laminas, 16 were characterized by focal destruction of elastic tissue, and 20 presented lesions of mixed character The elastic-tissue type of degeneration proved to be the predominant form in younger individuals (40 years and under), whereas the muscular type of lesion was more prevalent in the older group. In routine autopsy material, lesser degrees of these structural changes are often observed. The presumption is that dissecting aneurysm is the exceptional occurrence which complicates severe forms of a fairly common process. As previously mentioned, these lesions have a predilection for the ascending aorta and arch and appear to be accentuated by hypertension

Reparative changes occur with either form of medial damage The "mucinous" accumulation which may be such a conspicuous component of the lesion is also quantitatively a

variable one and is therefore regarded as a reactive change. Its presence is entirely nonspecific since similar accumulations occur in arteries in response to a wide variety of irritative processes. The increase of ground substance is not entirely acellular. Gsell (1928) observed stellate cells sparsely distributed in the basophilic accumulation and stated that, in old lesions, fibrous tissue replaces the mucoid material and repairs the medial defect. In common with other reparative reactions, there is increased vascularization, a mild perivascular influx of inflammatory cells, and peripheral (adventitial) fibrosis These features, greatly intensified, may also be seen in rheumatic, rheumatoid, and syphilitic aortitis. However, none of them predisposes to dissecting aneurysm (Weiss, 1935) The relative indolence of the reparative reaction in idiopathic medial degeneration is the reason for its vulnerability to dissecting aneurysm The bland reaction characteristic of the idiopathic degenerative process fails to narrow the vasa, to support them with sheaths of inflammatory tissue, or to bridge the gaps in the media Instead, the thin-walled vessels lie essentially unsupported *in a focus of medial weakening*, a condition suggesting great vulnerability to rhexis. That this indeed occurs is evident from reports of isolated intramedial hemorrhage; this is the circumstance that explains occurrence of dissecting aneurysm without intimal tears (Fig. 15-9).

Once intramedial hemorrhage has occurred, the sequence of events would seem to depend upon the extent of the degenerative change The extravasation, compressed and propelled by the tension to which the aortic wall is subjected, exploits its weaknesses. Thin-walled vasa in its path are interrupted, and with expansion of the hemorrhage an ischemic component is added to the vascular lesion. Rapid and accelerated progression results from either rupture of the intima overlying the intramural hemorrhage, or the opening of large arterial channels intramurally, or both Since there may be some question as to the possibility of hemorrhage into a structure which is continually under tension, it should be noted that the pulse wave in the vasa vasorum arrives *after* the main aortic pulse has passed. It is this asynchronism which permits them to function against the tension of the aortic wall. Hypertension would clearly increase the possibility

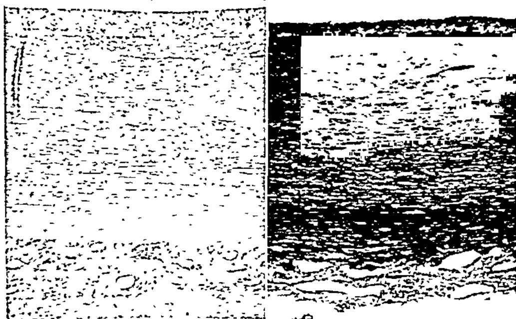

Fig 15-9. Aortic wall disclosing an organized and healed dissection tract in the outer portion of the media The defect is more obvious with the elastic tissue stain to the right. On the luminal side of the lesion, observe the condensation of elastic fibers and the relative pallor of the analogous portion to the left, an index of the depletion of muscle fibers. ×40.

of rhexis and would, in part, explain the high incidence of dissecting aneurysms in hypertensive individuals Nonetheless, it is clear that elevated arterial tension is merely a secondary factor in the pathogenesis of dissecting aneurysm

Etiologic Considerations. Although the cause of medial degeneration is unknown, a number of suggestive correlations may be noted. *Congenital anomalies* involving the vascular system, such as coarctation of the aorta, bicuspid aortic valve, and arachnodactyly, are found to be associated with an unusually high incidence of dissecting aneurysms suggesting that there may also be some congenital disturbance involving the vessel wall Indeed, Wolff (1932) and Holle (1947) reported medial elastic-tissue defects as the explanation for aortic aneurysms occurring in a 12-day-old and a 3-month-old infant respectively. Usually these defects do not become evident for years, and even decades, after birth That they then show a predilection for the metabolically more demanding proximal aorta suggests that they arise from impairment of the mechanism responsible for maintaining the integrity of the medial tissues Experimentally, this condition has been caused in rapidly *growing weanling* rats by incorporating *sweet pea meal in their* diet (Bachhuber and Lalich, 1955) In contrast, Duff (1932) observed no relation between the age and growth rate of the animals and the (much prompter) injurious effect of *diphtheria toxin* The report of Beaven and Murphy, of an unusually high incidence of dissecting aneurysm in hypertensive patients treated with *methonium* compounds if confirmed, gives grounds for speculating about an analogous metabolic influence in man

Schnitker and Bayer (1944) suggested a relationship between *pregnancy* and dissecting aneurysm since in their collected series more than half of 49 women younger than forty were pregnant Somewhat contrary evidence was furnished by Kinney et al (1945), who found that there was no increased incidence of dissection in 39 reported cases of coarctation in pregnancy

Infectious or granulomatous aortitis may be associated with dissecting aneurysm *Hypothyroidism* was suggested as a significant factor in the cases of Kountz and Hempelmann (1940); however, the dearth of substantiating data would indicate their findings to have been merely coincidence.

In the presence of medial disease and intramural hemorrhage, *mechanical factors* are important in the localization of the intimal laceration. Unusual stress occurs at two sites in the proximal aorta, which, according to Shennan are points of high incidence for the tears: (1) At the point where the right pulmonary artery crosses the aorta posteriorly, the posterior wall of the latter is regularly and rhythmically compressed by the systolic thrust of both channels. (2) The other site is the transition point from the relatively mobile arch to the fixed thoracic aorta where each pulsation results in localized bending stress.

MYCOTIC ANEURYSMS

Mycotic aneurysms are *localized dilatations of arteries* which result from infection and weakening of the vessel wall. The infecting source is usually intravascular, sometimes its origin is an extravascular focus in contact with the vessel wall Koch (1851) and Tufnell (1853) had reported earlier cases, but it was Osler (1885), describing multiple aortic aneurysms in a case of "malignant mycotic" endocarditis, who designated the lesions as *mycotic*. Since then, the term has come to be reserved for fungal infections, but tradition and long usage have perpetuated its application to a process which, with rare exceptions, is bacterial Although Osler was well aware of the bacterial nature of the endocarditis and the aneurysms in his case, Eppinger (1887) clearly established this bacterial origin and demonstrated that it was associated with inflammatory destruction of the vessel wall. This may occur by direct extension from an infected aortic valve or coarctation (so-called erosive aneurysm) or more remotely by an embolic mechanism The importance of embolization had been recognized by Virchow (1847) and Tufnell (1853) However, proper appreciation of its action awaited the dawn of the bacteriologic era. Minute infectious emboli may become entrapped in vasa vasorum and give rise to destructive inflammation of the vessel wall or, as Unger (1911) suggested, the infection may spread centrifugally from a nidus on the intimal surface.

The great majority of mycotic aneurysms are associated with bacterial endocarditis Almost 15 per cent of the latter complicate aortic coarctation. Other associated diseases are listed in Table 15-3.

The bacterial organisms which give rise to the associated aneurysms are the same as those causing the primary disease Alpha and hemolytic streptococci predominate, as they do in bacterial endocarditis, other common organisms are *Staphylococcus aureus, Diplococcus pneumoniae, Hemophilus influenzae,* and *Neisseria gonorrhoeae* Organisms tend to disappear from the lesions as they age The age and sex distribution of mycotic aneurysms reflect the incidence of the causative diseases, most cases occur in the second, third, and fourth decades Of 178 cases collected by Stengel and Wolferth (1923), 121 were in men and 57 in women

"Arteries in all parts of the body and of various sizes from the very largest to tiny unnamed vessels (the latter particularly in the brain), may be the seat of mycotic aneurysms Eppinger has called attention to their multiplicity stating that it is one of the most constant features of the condition" (Stengel and Wolferth) The aorta is most frequently involved, especially the root and the ascending segment. The pulmonary artery is relatively spared because of the infrequency of right-sided endocarditis. Table 15-4 lists the sites of 372 mycotic aneurysms

The type of endocarditis characterized by luxuriant *friable* vegetations is the form most likely to be complicated by embolic mycotic aneurysms Often there is widespread embolization and infarction. The size of the embolus determines the caliber of the vessel in which it lodges. Almost invariably embolic occlusion *involves vessels smaller than the aorta and* pulmonary arteries Favored sites of occlusion are *bifurcations, acute angulations,* or *points of rapid narrowing.* The mechanical effects of emboli are minor in the genesis of aneurysms, contrary to the opinion expressed before the role of bacteria was appreciated. The spread of infection from the embolus to the wall of the vessel results in inflammatory destruction, weakening, and subsequent focal dilatation (Fig 15-10). At times, this may happen so violently and so rapidly that there is rupture rather than herniation.

In large channels, occlusive embolization is less likely to occur and, except for direct extension (erosive aneurysm), infection of the vessel wall must take place in another manner. Direct penetration of the intact intima may be dismissed as unlikely; in the absence of an impacted shielding embolus, contact with circulating organisms could be, at most, fleeting These infections, therefore, arise from lodgment of septic emboli or bacteria in the vasa vasorum. *It will be recalled* that the nutrient arteries of the proximal aorta are derived from the coronary arteries, and this is the basis for

the particular vulnerability of the ascending aortic segment Coronary flow is maximal during diastole, and the proximity of their ostiums to the aortic valve makes them especially susceptible to embolization by fragments of vegetation broken off by the force of diastolic valvular closure The increased vascularization of the aorta which accompanies disease adequately explains its increased vulnerability to mycotic aneurysms

Mycotic aneurysms vary greatly in size and appearance They are usually small: millet-seed size in the cerebral arteries, no larger than a walnut in large arteries Occurring as they do in relatively young individuals, they are sharply demarcated from the contiguous, relatively undiseased arterial wall They are prone to rupture, this leads to free bleeding from aneurysms of cerebral, thoracic, or abdominal vessels and to perivascular hematomas or false aneurysms in peripheral lesions Arteriovenous fistulas are infrequent complications, bone erosion is not a feature of mycotic aneurysm

By the time the lesion can be examined, the infective embolus which led to it has often disintegrated, but when the embolus is demonstrable, its structure identifies it as a fragment or fragments of vegetation The inflammatory process in the vessel wall resembles that in the primary lesion, suppuration is uncommon There is an acute and subacute *periarteritis* and destructive *mesarteritis* Reparative reaction is poor and underlies focal dilatation and herniation of the vessel wall Within the sac, the intima is replaced by a fibrin membrane which may bear vegetations (Fig 15-10B). Microorganisms are demonstrable in acute lesions but become progressively more sparse thereafter While the entire process may be sharply delimited, there is often undermining of the adjacent intima Healing is usually associated with thrombosis and obliteration of the sac and, in peripheral arteries, the lumen as well Occasionally, as Eppinger described, there may be healing with reconstitution of the intima More commonly, healing is incomplete, and reflecting the smoldering nature of the infection, reparative changes of varying phases may be seen in individual as well as multiple aneurysms

Invariably, mycotic aneurysms develop in patients already ill, but the specific clinical findings associated with them depend upon the site of vascular involvement. If this lies deep within the body, the condition may not be suspected until post-mortem examination. However, a parasternal area of abnormal pulsation in a case of bacterial endocarditis permitted Stengel and Wolferth to make an antemortem diagnosis of mycotic aneurysm of the aortic arch The roentgenographic appearance enabled Nicholson (1940) to recognize a my-

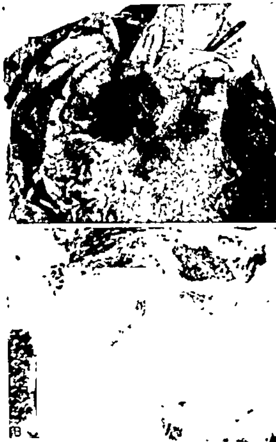

Fig. 15-10 A. Heart Mycotic aneurysm of right coronary artery. The probe passes from the ostium in the aorta through a transected part of the coronary aneurysm. Observe also the severe fibrinous pericarditis The patient, a victim of subacute bacterial endocarditis, died of pericardial hemorrhage. (*Courtesy Dr. Albert Hirst, Jr.*) B. Mycotic aneurysm of coronary artery. The vessel wall is entirely necrotic and can only be identified by the darkly staining elastic fibers to the right of the photograph. Proceeding to the left there is an abrupt bulge in the completely necrotic vessel wall (downward in the photograph). The aneurysm lining consists of fibrin admixed with purulent exudate; similar material permeates the periarterial tissues ×40

The great majority of mycotic aneurysms are associated with bacterial endocarditis. Almost 15 per cent of the latter complicate aortic coarctation. Other associated diseases are listed in Table 15-3

The bacterial organisms which give rise to the associated aneurysms are the same as those causing the primary disease Alpha and hemolytic streptococci predominate, as they do in bacterial endocarditis; other common organisms are *Staphylococcus aureus, Diplococcus pneumoniae, Hemophilus influenzae*, and *Neisseria gonorrhoeae*. Organisms tend to disappear from the lesions as they age The age and sex distribution of mycotic aneurysms reflect the incidence of the causative diseases, most cases occur in the second, third, and fourth decades Of 178 cases collected by Stengel and Wolferth (1923), 121 were in men and 57 in women

"Arteries in all parts of the body and of various sizes from the very largest to tiny unnamed vessels (the latter particularly in the brain), may be the seat of mycotic aneurysms. Eppinger has called attention to their multiplicity stating that it is one of the most constant features of the condition" (Stengel and Wolferth) The aorta is most frequently involved, especially the root and the ascending segment The pulmonary artery is relatively spared because of the infrequency of right-sided endocarditis. Table 15-4 lists the sites of 372 mycotic aneurysms

The type of endocarditis characterized by luxuriant friable vegetations is the form most likely to be complicated by embolic mycotic aneurysms Often there is widespread embolization and infarction. The size of the embolus determines the caliber of the vessel in which it lodges. Almost invariably embolic occlusion involves vessels smaller than the aorta and pulmonary arteries. Favored sites of occlusion are *bifurcations, acute angulations*, or *points of rapid narrowing*. The mechanical effects of emboli are minor in the genesis of aneurysms, contrary to the opinion expressed before the role of bacteria was appreciated The spread of infection from the embolus to the wall of the vessel results in inflammatory destruction, weakening, and subsequent focal dilatation (Fig. 15-10). At times, this may happen so violently and so rapidly that there is rupture rather than herniation.

In large channels, occlusive embolization is less likely to occur and, except for direct extension (erosive aneurysm), infection of the vessel wall must take place in another manner. Direct penetration of the intact intima may be dismissed as unlikely; in the absence of an impacted shielding embolus, contact with circulating organisms could be, at most, fleeting These infections, therefore, arise from lodgment of septic emboli or bacteria in the vasa vasorum It will be recalled that the nutrient arteries of the proximal aorta are derived from the coronary arteries, and this is the basis for

cally, these cases are characterized by *primary degeneration of the lamina elastica of the media* more commonly than those of older people; the latter are characterized by *primary degeneration of the smooth muscle*, although both forms of degeneration commonly coexist (Gore, 1953).

Recently, the treatment of hypertension with potent ganglionic blocking drugs, particularly in the "malignant" phase, has been suggested as a cause for dissecting aneurysm of the aorta. In a single series of 44 patients so treated who ultimately succumbed and were examined at necropsy, 20 per cent had sustained this complication (Beaven et al.). Since this incidence greatly exceeds that expected in untreated cases, it was suggested that the fluctuations in blood pressure induced by the therapy, or a specific biochemical effect of the drugs, might be the means of its production. It seemed unlikely that prolonged life permitted by the therapy allowed the complication to develop when it would not have occurred otherwise In the author's experience, this high incidence of dissecting aneurysm during treatment of hypertension has not been observed

In other circumstances with fluctuating blood pressure, such as pheochromocytoma, dissecting aneurysm has occurred occasionally

CONGENITAL ABNORMALITIES. These commonly coexist with dissecting aneurysm, particularly when dissection occurs early in life, and may indicate a fundamental underlying weakness in the vascular system. The most commonly associated anomalies of the cardiovascular system are *coarctation of the aorta* and *bicuspid aortic valve*. Patients with *Marfan's syndrome*, which shows many disturbances of the body including arachnodactyly and dislocation of the lens of the eye, commonly succumb to dissecting aneurysm of the aorta The experimental production of dissecting aneurysm of the aorta by the feeding of legumes (*Lathyrus odoratus*) or their destructive principles (aminonitriles) also produces marked skeletal and connective tissue defects and suggests a general ground-substance disorder This observation led Bean and Ponseti (1955) to review their series of 20 cases of dissecting aneurysm studied at autopsy, they found concurrent skeletal deformities in 35 per cent This is a lead not well explored in

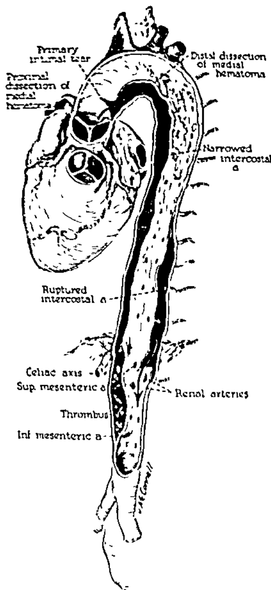

Fig. 15-11. Representation of dissecting aneurysm illustrating mechanisms which produce its clinical features

previous clinical reports, which may alert physicians to the diagnosis and stimulate investigators to further search for the causes of dissecting aneurysm.

STRESS Physical and emotional stresses, including hard manual labor, straining at stool, swimming, coitus, vomiting, and arguments, have immediately preceded the onset of the symptoms of dissecting aneurysm and may have facilitated the tearing of the aortic intima, allowing the blood to gush into and extend the preformed rent in its wall

cotic aneurysm associated with aortic coarctation. Lesions of the cerebral arteries lead to clinical findings indistinguishable from those due to other forms of cerebrovascular accident. In superficial or accessible vessels, the situation should be readily recognized. Lesions appear as pulsating inflammatory swellings a few days to several weeks subsequent to a sudden embolic onset. Some may rupture rapidly but, more often, several weeks elapse before hemorrhage is indicated by rapid enlargement, loss of distinct outline and painful tense swelling. Distally, arterial pulsation is often lost; but gangrene is infrequent.

The prognosis is that of the underlying disease and has improved enormously with the availability of antibiotics, yet rupture of a mycotic aneurysm was the principal cause of death in 17 of 408 penicillin-treated cases of subacute bacterial endocarditis. Prior to penicillin, Goadby et al. found only two reported recoveries from mycotic aneurysm and bacterial endocarditis. Aneurysms due to causes other than endocarditis were more often successfully treated Present-day treatment includes antibiotic administration for the infection and surgical excision of accessible lesions Prompt and effective treatment of bacterial endocarditis has undoubtedly reduced the frequency of bacterial aneurysms but these lesions may still appear, even after the completion of presumably adequate antibiotic therapy.

CLINICAL ASPECTS

DISSECTING ANEURYSMS

Definition. A dissecting aneurysm is a false sac within the wall of an artery, usually *the aorta*, less commonly *the pulmonary artery, a branch of the aorta*, or, rarely, *a smaller artery*. Ordinarily the false sac is penetrated by the circulating blood column from the lumen of the vessel, the pressure of which frequently distends the sac until it ruptures, either outwardly (through the adventitia) or inwardly (reentering the lumen through the intima) Burchell calls the lesion *"a dissecting hematoma"* because of the absence of a true expanding and limiting wall characteristic of other aneurysms. Nevertheless, two centuries of designation as a dissecting aneurysm will probably preserve this term with the understanding that it refers to *a false aneurysm* (Fig. 15-11).

History. The earliest recognition of dissecting aneurysm was by the morbid anatomists of the seventeenth and eighteenth centuries (Sennert, Morgagni) but its clinical recognition has come only within the last century (Latham). The ruptured aneurysm, an obvious cause for sudden death, was a gratifying and encouraging finding for the early anatomists and served to justify and promote dissection-study of human remains At least two of Morgagni's cases of aortic aneurysm rupturing into the pericardial sac appear to have been of the dissecting type. Nicholls' report of the post-mortem examination of King George II of England (1760) shows that the king had a dissecting aneurysm of the aorta, although his death resulted from rupture of the right ventricle. Latham et al. (1856) reported their ante-mortem diagnosis of a dissecting aneurysm of the aorta affecting a 51-year-old man, who was seized with "a sudden and violent pain as though . . . his chest were torn open . . . seemed to dart . . . down the left side of the spinal column . . . after a repetition of the lacerating pain . . this time . . from scapula to scapula . . ," and confirmed this clinical diagnosis by observation of the aorta after the patient's death. In the century which has passed since this first diagnosis of a dissecting aneurysm of the aorta was made, the frequency and accuracy of its recognition has improved but it is still identified in only one-fourth to one-half of the cases which occur

Cause. Dissecting aneurysm occurs mainly during later life; the average age at onset is about 50 years It has been described at both extremes of life, in a patient of 100 years (Shennan) and in an infant of 12 days (Wolff). It affects men at least twice as frequently as women, except in the eighth and ninth decades when it is women who are predominantly affected (Shennan) It is more common in the white race.

HYPERTENSION. Ordinarily, elevated blood pressure precedes the development of dissecting aneurysm of the aorta and commonly persists after the dissection occurs unless masked by shock. In most instances, the heart has already hypertrophied before dissection takes place. In persons under 40 years of age, hypertension is not so uniformly present. Pathologi-

within the first few days Nontraumatic ecchymoses are occasional but striking findings resulting from local disturbances in circulation.

Systemic hypertension almost uniformly precedes the acute episode, except in the occasional cases which occur early in life It commonly persists as an important physical finding after the acute episode and should be expected, unless masked by the severity of the clinical shock. *It is remarkable how high the blood pressure may be, even when the patient appears to be suffering from shock*, a paradox useful in diagnosis. In those instances where the shock syndrome has concealed the hypertension from the examiner, its previous presence is evidenced by retinal arteriolar changes Except in young persons, *left ventricular enlargement* is almost always present The left ventricle is more accessible to examination than under normal circumstances, in that its activity is transmitted to the chest wall with unusual clarity and fidelity The apex is displaced downward and toward the left. The pressure of the enlarged left ventricle upon the diaphragm changes its mechanical advantage upon the lower rib cage, impairing excursion of the medial portion of the left costal margin When associated dilatation is advanced, systolic retraction medial to the apex results from increased ejection and produces *a see-saw motion of the chest wall* with its fulcrum about an inch medial to the maximal apical thrust.

The sudden development of *an aortic diastolic murmur*, often with concurrent *systolic murmur*, in the presence of the other clinical features, is virtually pathognomonic for dissecting aortic aneurysm. It may result from aortic valvular distortions produced by the dissecting hematoma (the usual explanation cited for this sign) but may also occur when the hematoma does not distort the valves (Resnik et al) Letulle explains that the ingress and egress of blood from the false sac, with the rising and falling pressure of the true lumen of the aorta, can cause the double murmur in the instances where no valvular distortion is demonstrable This may be the actual cause for this sign in all cases. Unfortunately, this valuable sign is not uniformly present, if found, it will confirm the diagnosis

The widening of the aorta is not easily demonstrable by physical examination, but its pulsations, better transmitted by the wide, false sac to the chest wall, may become conspicuous. Logue et al (1952) demonstrated that a transmitted pulsation of the sternoclavicular joints was diagnostic of dissecting aneurysm when the clinical findings were otherwise consistent and when syphilitic aneurysm, partial rupture of saccular aneurysm of the aortic arch, and anomalous right aortic arch could be excluded by other means. Secondary rupture of the false sac into the pericardium rapidly produces *cardiac tamponade* and frequently immediate death. Prompt increase in venous pressure and congestion, paradoxical pulse, faint heart sounds, some increase in heart dullness with reduction in the accessibility of the ventricular pulsations, a friction-rub, and falling blood pressure, are the evidences of tamponade. Rupture into the pleural space, more commonly the left, gives the signs of free pleural fluid

Sometimes abdominal symptoms and findings predominate to such an extent that a primarily "surgical" catastrophe within the abdomen seems to be present. Since the vascular supply to any abdominal organ may be occluded by the dissection, almost any acute abdominal emergency can be simulated. The syndrome depends upon the course of the dissection, the organ rendered ischemic, and the site and extent of extravascular hemorrhage. Peritoneal irritation arises from seepage of blood into the abdominal cavity, this, together with the concurrent pain and vomiting, may encourage the surgeon to explore the patient fruitlessly and with great mortality risk

Paralysis of the extremities, particularly the legs, arises from both occlusion of their major vessels by the dissection and spinal-cord damage incident to interruption of the intercostal, lumbar, and anterior vertebral arteries. When the major vessels to the extremity are occluded, there is motor and sensory paralysis, absent pulse, pallor, and clamminess of the skin, which is sometimes marbled or shows a mottled cyanosis Distal gangrene may supervene. *Spinal-cord damage* results in neurological changes below its level, it is manifested by weakness, paresthesias, pain, sensory and reflex changes, and sometimes inability to void.

Neurological alterations referable to the brain often coexist with dissecting aneurysm and result from both interruption of vertebral and

MISCELLANEOUS *Pregnancy* appears to be a contributing factor (Mandel et al.), since half of the women affected by dissecting aneurysm before the age of 40 years were either pregnant or in the early puerperium at the time the dissection occurred.

A few cases of dissecting aneurysm have been reported following *total thyroidectomy* in patients with severe hypertension (Kountz et al). It has been suggested that further observation may demonstrate a relationship between the endocrine glands and aortic cystic degeneration.

Arteriosclerosis often coexists with dissecting aneurysm of the aorta, as might be expected from the age at which most dissections become manifest. Syphilis, though previously under suspicion, is no longer considered to be a prominent factor in the causation of dissecting aneurysm

Symptoms. Pain is the outstanding symptom of aortic dissection, occurring in almost every patient who remains conscious and out of profound shock. The pain ordinarily begins in the anterior chest, arising beneath the sternum and extending into the back, particularly into the interscapular areas Its onset is usually sudden, often coinciding with exertion, vomiting, emotional display, or other stresses Ordinarily severe and terrifying, the pain is usually of a *tearing* quality, which suggests to the patient that he has suffered internal damage placing his life in immediate peril *The pain spreads*, as would be anticipated from the course of the dissection, *into the head and neck, abdomen, or the extremities* Occasionally, it is felt predominantly or exclusively in the back or abdomen, less commonly it is limited to the head, neck, or extremities The pain is persistent and little affected by external circumstances or the physiological functions of other parts of the body. It even resists fairly large doses of narcotic drugs

A *shock syndrome* with profound prostration may overshadow the patient's pain, and in some instances is the presenting complaint It is an outstanding clinical accompaniment in one-third to one-half of the cases The blood pressure recorded is often higher than symptoms would lead one to anticipate because of the significant elevation which antedated the dissection; a considerable fall still allows a fair level of blood pressure to remain.

Dyspnea is an important clinical expression of the disease in approximately one-half the patients. It attracts special attention because the usual respiratory symptoms and findings which accompany dyspnea resulting from other causes are absent. *Cyanosis* appears occasionally.

Neurological symptoms are fairly frequent and often helpful diagnostically. *Confusion* and *disorientation* affect up to one-third of the patients. *Coma* and *collapse* affect up to one in five patients after aortic dissection Neurological reactions arise from both the altered perfusion of the brain and spinal cord incident to the shock syndrome and the obstruction of the lumens of major vessels from the pressure of the expanding hematoma. *Paresthesias*, especially of extremities, are the complaint of one patient in ten and contribute diagnostic clues localizing the lesion. *Weakness* of the lower extremities, with or without sensory changes, may occur; this arises from occlusion of the lower aorta and its branches with resultant ischemia of the extremity itself, or from occlusion of intercostal vessels with resultant spinal cord ischemia or infarction *Hoarseness* from recurrent laryngeal nerve involvement occurs only occasionally but helps make the diagnosis when present.

Signs. Immediately following an acute dissection of the aortic media, the patient's appearance indicates an acute catastrophe He is anxious, fearful, and pale (with an *ashlike grayness*), perspires on a cold, clammy skin and breathes rapidly, often grunting during respiration. There is a rapid pulse which may be either thready or full. There may be a *reduplication of pulse* in a carotid artery (Nissim, 1946) or other arteries, the second pulsation representing a transmission delayed by expansion of the hematoma. A difference in the blood pressure in the arms, or reduction of the relative blood pressure in the legs, may result from partial occlusion of the aortic lumen by the medial hematoma

In occasional cases, particularly where the dissection has been of lesser degree or the onset more gradual, the shock syndrome is less evident The course of the shock, once present, is quite variable, sometimes spontaneously abating after a few hours but often severe and progressive until death.

Initially fever is absent but usually develops

vals, sagging of the S-T segment, and flattening and inversion of the T waves. A completely normal electrocardiogram is unusual in dissecting aneurysm and should lead one to question the clinical diagnosis.

Radiographic findings in dissecting aneurysm of the aorta, although rarely diagnostic in themselves, are often helpful. Unfortunately, the precarious clinical condition of the patient often precludes taking the patient to the radiology department. Bedside techniques, particularly if the patient must be kept recumbent or the tube must be brought closer than 6 ft, frequently induce such distortion for the finished roentgenograms as to make them valueless. Widening of the aortic shadow is the most common radiographic expression of dissecting aneurysm, aside from the usual concurrent left ventricular enlargement. If, luckily, previous chest films are available, their technique should be repeated as to patient position, exposure factors, and respiratory phase, so that comparison of the aortic shadows can confirm the diagnosis If intimal calcification is fortuitously present, the thickness of the aortic wall (normally 2 to 3 mm) can be measured readily and any increase due to the medial hematoma can be appreciated In some instances, the true lumen of the aorta has been outlined by angiocardiographic techniques which accurately delineate the site and extent of dissection, but the hazards of these techniques require sober consideration In chronic dissecting aneurysm, calcification of the limits of the false sac rarely occurs but, if present, outlines the sac clearly for diagnostic consideration. The blood column of the true aortic lumen produces a denser radiographic shadow than the dissected portion and thereby facilitates its identification. The false sac may pulsate but does not do so invariably. Serial examinations which allow identification of advancing dissection, particularly around major aortic branches, may confirm the diagnosis but are extremely difficult to obtain in the usual patient because of the gravity of his illness

Course and Prognosis. The usual course of dissecting aneurysm of the aorta is short, death commonly occurs within an hour to a fortnight after the onset, with the patient in a state of circulatory collapse. Death may be accelerated by congestive heart failure, uremia, pulmonary infection or infarction, and neurological complications Death may be delayed and in occasional instances avoided when secondary rupture of the false sac into the vessel fortuitously allows reentry of the blood through the intima into the lumen of the vessel. Such a reentry, while prognostically favorable, does not invariably prevent the external rupture and resultant exsanguination or the secondary proximal rupture into the pericardium with cardiac tamponade. Occasional patients have lived several months and even (rare instances) several years after the initial dissection; in these instances death has resulted ultimately from other causes, but most commonly from further dissection or congestive heart failure.

Differential Diagnosis. Dissecting aneurysm, because of its polymorphous distribution, course, gravity, and relative infrequency, simulates many other disorders and often leads the physician into a diagnostic trap. It is most commonly confused with myocardial infarction or pulmonary embolism. It often simulates various abdominal catastrophes and motivates useless, hazardous surgical intervention. Neurological and peripheral vascular syndromes need to be carefully distinguished Guided by familiarity with the manifestations of dissecting aneurysm, aware of its ability to mimic more frequent disorders, and prepared by its inclusion for differential consideration in the several syndromes which it may present, the physician will recognize this disease more frequently and mistreat it less often. The progression of symptoms and findings, consistent with the results of an expanding medial hematoma with progressive occlusion of sequential branches of the aorta, is very helpful to the physician attempting to diagnose the patient's illness.

Treatment. Conservative treatment for dissecting aneurysm is primarily supportive and symptomatic. It includes bed rest, morphine, and oxygen. All available means for combating the profound shock are often found wanting Blood transfusions will partially replace the loss into the false sac and through external rupture. Pressor amines which avoid concurrent increase in myocardial irritability, such as levarterenol (Levophed), metaraminol (Aramine) and mephentermine (Wyamine) have been extensively employed Since all that pressor amines can accomplish is reduction in the volume of the vascular bed, it is not remark-

Fig. 15-12. Electrocardiogram made a day after symptoms of dissecting aneurysm of the aorta appeared. The tiny Q_2 and deeper Q_3-aVF, and the elevated S-T segments suggest a diagnosis of posterior myocardial infarction Nonspecific T-wave inversion in anterior and lateral leads suggest ischemic changes difficult to reconcile with a posterior infarction alone. Two days after this electrocardiogram was taken, death occurred from proximal extension of a dissecting aneurysm of the aorta and rupture into the pericardium The left coronary artery was caught in an ecchymotic and suffused area at the base of the aorta so that its lumen was compromised by the extrinsic pressure; this explains the simulation of ordinary myocardial infarction.

carotid circulation by the pressure of the aneurysmal mass and concurrent vascular disease of the brain independent of the dissecting aneurysm. Hemiplegia, hemiparesis, convulsions, disturbed consciousness, vertigo, aphasia, and blindness may occur The neurological findings are often bizarre and difficult to correlate, even when the detailed anatomical findings are available. Their unusual character should suggest the diagnosis.

The frequency of neurological changes recorded varies widely in different series of patients and somewhat with the enthusiasm with which they are sought. About one-half the cases will yield abnormal data after careful examination. While, in many instances, the neurological alterations are nonspecific by themselves, they greatly support the diagnosis when the clinical picture is otherwise compatible.

Laboratory Findings. Leucocytosis is usually found within a few hours after aortic dissection and frequently approximates 20,000 cells/mm^3. Marked leucocytosis ranging around 30,000 cells sometimes occurs; occasionally higher levels are noted *Normochromic anemia* is common. The urine is frequently abnormal, with albumin, casts, and red blood cells demonstrable in most cases. With frank involvement of the renal arteries, *gross hematuria* is usually present as well as a concurrent rise in the nitrogenous residues of the blood *Jaundice* is occasionally present. When *pleural effusion* is present, thoracentesis frequently produces bloody fluid. In some instances, a blood-tinged pleural fluid occurs without frank perforation of the false sac of the aneurysm.

The serological tests for syphilis are ordinarily negative and, even when they are positive, no relationship of syphilis to dissecting aneurysm seems likely. Actually, the inflammatory lesions of luetic origin probably render dissection less likely because scarring tends to fuse the layers of the aorta together.

Electrocardiograms are usually abnormal but without specificity for this lesion. Various disturbances of rhythm, including atrial fibrillation, and disturbances of intracardiac conduction may be present The most common electrocardiographic alterations are those of the concurrent left ventricular hypertrophy (Levinson et al) An erroneous electrocardiographic diagnosis of myocardial infarction is frequently made from nonspecific S-T and T-wave changes In about one-fourth of the cases, there are patterns indicating coronary insufficiency Compression of a coronary artery by hematoma, most commonly a vessel of the posterior wall (as occurred in the instance of which the electrocardiogram is shown, Fig 15-12), compromises the lumen and produces pathological alterations in the myocardium identical with those caused by occlusion of the coronary lumen. Blood leaking into the pericardium produces the typical pattern of pericarditis In instances where kidney damage has resulted, electrocardiographic alterations are those seen in uremia and electrolyte disturbance, including prolonged Q-T inter-

reports (Table 15-6), more than one-half involved the aorta, intracranial, superior mesenteric, or femoral arteries. Any artery in the body may be attacked Mycotic aneurysms may be multiple (394 aneurysms in 350 cases) and would probably be multiple more frequently were it not for their own lethal course, as well as for the underlying mortal disease They are usually saccular, varying greatly in size They frequently rupture and bleed massively or may serve as the site for a thrombus which occludes the lumen of the vessel of origin. Histologically there is destruction of the vessel wall which is invaded by acute and chronic inflammatory cells

Clinical Features. In the usual case, a mycotic aneurysm arises in a patient who already shows signs of a serious, septic systemic disease The length of illness preceding its onset is variable, depending upon the virulence of the primary infection. The patient has usually lost weight and displays general malaise, lack of energy, fever, and a sallow complexion Endocarditis, usually with bacterial involvement, is commonly present. The course of the underlying disease is suddenly interrupted by an embolic episode characterized by local pain, signs of ischemia peripheral to the occlusion, increase in pulse rate, and fever. Later, as the embolic signs begin to subside, there is a recrudescence of local signs including increase in pain and development of a pulsating mass often manifesting a *bruit* Rupture may occur after a variable period of time, often within a week after its origin, or the aneurysm may thrombose and go on to spontaneous healing by fibrosis In some instances, the several stages may follow in such rapid succession that massive bleeding appears to herald its onset

The clinical syndromes presented by mycotic aneurysms in specific locations are distinctive When the *abdominal aorta* is involved, there is usually deep visceral pain, sometimes associated with a pulsatile mass and thrill. There may appear to be an acute intraabdominal "surgical" catastrophe, particularly when rupture produces shock or bleeding into the bowel Mycotic aneurysm of other intraabdominal arteries, such as the mesenteric, hepatic, or splenic, present similar pictures When the *thoracic aorta* is involved, there is deep substernal chest pain, often compression of contiguous structures, and often rupture with sudden death Rupture may occur into the trachea or esophagus with resultant bloodspilling, either into a pleural cavity (usually the left) with the rapid development of bloody fluid compressing the lung, or into the pulmonary vessels with resultant pulmonary hypertension and hemoptysis It may simulate other acute thoracic catastrophes, such as myocardial infarction, pulmonary embolism, or dissecting aneurysm of the aorta When *intracranial arteries* are involved, the syndrome often simulates the rupture of a congenital aneurysm with subarachnoid bleeding, or it may resemble an ordinary intracranial hemorrhage with hemiparesis or hemiplegia *Headache* may precede other symptoms. It is particularly true of intracranial involvement that the course is often exceedingly short and with the several stages of aneurysm formation telescoped one upon the other, so that the massive bleeding first announces the disease When a vessel of an extremity is involved, particularly

able that their action is only temporary and is soon overcome by the further progress of the disease.

Anticoagulant therapy is ordinarily considered to be contraindicated because it destroys the clotting potential of the individual and his ability thereby to seal small ruptures in the arterial walls. For this reason, differentiation of dissecting aneurysm from myocardial infarction, where such therapy is commonly employed, has been considered of greatest importance. Recently Freeman (1956) has suggested a reevaluation of this concept, suggesting that anticoagulant therapy might be a useful adjunct facilitating reentry of the blood from the false sac by a secondary intimal defect, either spontaneously or surgically, back into the true lumen. It is dubious whether the clotting potential of the individual is much protection when external rupture of a dissecting aneurysm occurs and it is not likely that clotting within the false sac is much protection either. Nevertheless, until further experience has been accumulated, it is generally recommended that anticoagulants be withheld from such patients.

The inadequacy of conservative measures in the control of the shock and the frightfully poor prognosis has encouraged surgeons to try a number of heroic mechanical procedures for correcting the defect. In general, these procedures include the creation of a secondary ostium communicating with the true lumen of the vessel near the lower end of the false sac, with closure of any remaining sac beneath this ostium with or without resection of a portion of the involved aorta and replacement by homograft or other aortic substitute. In a few instances, the results of such operations have been gratifying (DeBakey et al.; Swan et al., 1950) for the short period of subsequent observation. Their eventual worth will be better evaluated after more cases have been followed for a longer time. Unfortunately, the risk of such procedures is great as might be anticipated from the poor clinical condition of the candidates, the magnitude of the procedure, and the natural history of the disease.

MYCOTIC ANEURYSMS

A mycotic aneurysm is an abnormal local dilatation of an artery weakened by a suppurative process, produced by infection, within its wall. The term "mycotic" was applied by Osler (1885) to distinguish those aneurysms which result from infection from the larger group of aneurysms which result from degeneration or trauma The term *mycos* (derived from the Greek μυκος meaning mushroom or fungus) may be considered inappropriate because most of these aneurysms arise from bacterial infections, principally from streptococcal emboli of bacterial endocarditis, pneumonia, septicemia, or abscesses, rather than from fungus infection, such as actinomycosis or cryptococcosis, from which they rarely originate, but its authoritative origin and long usage will probably preserve its designation as "mycotic."

Origin. Most mycotic aneurysms afflict young men Three out of four patients affected are men, and nine out of ten are under 40 The source of the infection may be any suppurative focus within the body but in more than 90 per cent of cases is bacterial endocarditis or pneumonia (Table 15-5). Preexisting vascular defects, such as coarctation or damage to the vessel wall, facilitate aneurysm formation but are not prerequisite.

Pathology and Pathogenesis. The majority of mycotic aneurysms result from the infection carried to the wall of a major artery by a bacterial embolus. The few others arise from the direct extension of a neighboring abscess In the series of 350 cases compiled from published

Aortic aneurysms

K. K. DATEY

The word "aneurysm" is derived from the Greek word "aneurusma," which means "to widen" or "to dilate"

Aneurysms, chiefly *traumatic*, were known to Galen Fernel (1554) was the first to associate arterial dilatations with aneurysms. Both Fernel and Paré (1564) associated aneurysms with syphilis. Morgagni (1761) further emphasized the role of syphilis in the development of aneurysms of the aorta Riva (1670) discussed the nature and character of aneurysms while Lancisi (1707) discussed their causes and types *Fusiform aneurysms* of the aorta were demonstrated by von Haller in the eighteenth century Nicholls (1761) reported the post-mortem findings in a case of dissecting aneurysm of the thoracic aorta Hunter (1762) described *arteriovenous fistulas* The discovery of *Treponema pallidum* in sections of tissue from patients with syphilitic aortitis and the development of the Wassermann reaction, were further milestones Lately, an increasing awareness of the condition and the development of modern diagnostic techniques, e g., electrokymography, angiocardiography, aortography, and cardiac catheterization, have made the detection of aneurysms more definite, this is particularly true of aneurysms of the sinus of Valsalva, which hitherto were usually undiagnosed ante-mortem. Major progress in the field of aneurysms is represented by the development of modern surgical methods (replacement by grafts, etc), which have revolutionized their treatment.

DEFINITIONS

An aneurysm may be defined as a localized or diffuse abnormal outpouching of an artery. An aneurysm of the aorta may be "true" or "false." A "true aneurysm" is one in which the walls of the dilatation are formed by the coats of the artery. The term "false aneurysm" is applied to those dilatations in which the wall has undergone rupture, but exsanguinating hemorrhage has been prevented by the restraint of adherent adjacent structures, which have formed a new false wall. True aneurysms may be of the following types:

1. *Diffuse aneurysm* This implies generalized dilatation of an artery.

2 *Saccular aneurysm* Saccular aneurysms are saclike dilatations which communicate with an artery by an opening that is small in comparison with the size of the sac Such dilatations are restricted to a segment of an artery or part of its circumference

3 *Other aneurysms* The aorta may establish communication with a vein, the pulmonary artery, or the chambers of the heart (either a ventricle or an atrium). These communications have also at times been included under aortic aneurysms

False aneurysms are best exemplified by the *dissecting aneurysms*. These are caused by splitting of the media of the aorta by extravasated blood that has penetrated between its coats from the lumen of the vessels or from the vasa vasorum.

INCIDENCE

Aneurysms are found in about 1 to 3 per cent of all bodies submitted for autopsy.

Age. About 90 per cent of aortic aneurysms are detected in patients between 40 and 70 years of age In a series of 230 aortic aneurysms syphilitic involvement was the predomi-

the femoral artery, the serial stages of aneurysm formation, from the initial embolism through that of the expanding painful expansile mass to rupture or healing by fibrosis, are most easily seen. The onset is frequently characterized by pain, numbness, coldness, pallor or mottled cyanosis, imperceptible arterial pulses below the lesion, collapsed superficial veins, and loss of the motor power in the leg. Later, there is recrudescence of pain with an expanding tumor mass at the site of the initial embolism, often a bruit, peripheral edema, and signs of peripheral neuropathy from compression of the nerves The bleeding after rupture follows the fascial planes of the leg which often limit the extent of hemorrhage and form a false sac Death from *shock* is frequent. In rare instances, a mycotic aneurysm may rupture into the adjacent vein, thereby forming an *arteriovenous fistula* which can later cause cardiac failure In those instances where the aneurysm becomes thrombosed, fibrosis later occurs but leaves the extremity with chronic arterial insufficiency

The laboratory findings in patients with mycotic aneurysm show the usual alterations expected with infection. The specific causative organism can often be cultured from the blood, or, after surgical removal, from the wall of the aneurysm. Roentgenograms, though often unnecessary, may reveal the outline of the aneurysm, particularly in the thorax, and, after proximal injection of contrast material into the artery, will indicate the exact location of the lesion.

TREATMENT

Many mycotic aneurysms can be prevented by adequate treatment of the primary infection. Frequently, suitable *antibiotics* will curtail the growth of the organism, so that it will be unable to continue to destroy the arterial wall. After appropriate antibiotic therapy, therefore, the aneurysm may not develop despite the lodgment of a septic embolus, or will cease to expand once it has started. In some instances, however, the aneurysm already may be fully formed before suitable prophylactic therapy can be effective In such instances, surgical intervention is essential to remove the aneurysm. Sometimes, special procedures are necessary to reestablish the continuity of the vessels Preliminary or subsequent *sympathectomy* may be necessary to insure adequate circulation distal to the area involved by the aneurysm. Regardless of the therapy employed for the treatment of the aneurysm itself, the patient requires prolonged treatment and convalescence in order to overcome the underlying infection and recover from the ravages of a severe generalized illness.

Pressure on Nerves. Pain due to pressure on the nerve roots is neuralgic in type. Pain in the neck is probably caused by abnormal afferent impulses reaching the cervical spinal cord as a result of distention of the transverse arch. Aneurysms of the descending aorta are more likely to press on spinal nerve roots

Coronary Pain The involvement of coronary vessels, particularly at their openings in the sinus of Valsalva, may produce pain which in character and distribution is similar to and indistinguishable from "angina pectoris"

NEUROLOGICAL MANIFESTATIONS *Left Recurrent Laryngeal Nerve.* This nerve, because of its close proximity to the aortic arch, is frequently involved in aneurysms of the arch The abductor fibers are involved earlier than their adductor counterparts and therefore *the left vocal cord is, at first, in the position of adduction* During phonation, the right vocal cord meets the left and thus the voice may remain normal. Hence, a laryngoscopic examination is necessary to detect, at an early stage, the involvement of the left recurrent laryngeal nerve, since this may be associated with even a small aneurysm. Later, as the pressure increases, adductor fibers are also damaged, and consequently the left cord remains immobile in "cadaveric position," midway between full inspiration and full expiration. It is at this stage that the patient develops *hoarseness,* which is present in about 20 per cent of patients with aneurysms of the arch. Hoarseness may be the first presenting symptom The voice may

TABLE 15-7. PERCENTAGE DISTRIBUTION OF AORTIC ANEURYSMS

Location of aneurysm	*Author's series (Datey) (63 cases)*	*Turner's series (146 cases)*
Ascending aorta	32	70.5
Aortic arch	40	
Descending aorta	12	18.5
Abdominal aorta	7	5.5
Multiple aneurysm (Including aneurysms of the aortic bulb in author's series)	9	5.5

nant cause and accounted for 82 per cent of the cases, atherosclerosis for 14 per cent, combined syphilis and atherosclerosis for 1.3 per cent; and mycotic and traumatic for the rest. Most of the arteriosclerotic aneurysms were located in the abdomen (63 per cent), while the aortic arch and thoracic aorta were involved in 37 per cent of the cases. Of the syphilitic aneurysms, however, 89 per cent were in the thoracic aorta (85 per cent of these in the ascending aorta and arch, 15 per cent in the descending aorta), while the abdominal aorta was involved in only 11 per cent

Distribution. Table 15-7 indicates the distribution of aortic aneurysm as found by Turner and the author in series of 146 and 63 cases, respectively

ANEURYSM OF THE THORACIC AORTA

The aorta may undergo two types of dilatations, viz., the diffuse and the saccular (or circumscribed).

Diffuse Aneurysm. General dilatation of the aorta (diffuse aneurysm) is often extensive, but seldom reaches an enormous size Such an aneurysm may be associated with diminished coronary circulation, which in turn leads to cardiac pain Pulsations may be visible in the suprasternal notch. The roentgenogram shows unfolding and general dilatation of the aortic arch When the aortic ring is not stretched, the dilatation of the aorta beyond it may produce a systolic murmur. If there is no complicating aortic incompetence or associated coronary disease, patients with diffuse aneurysms may lead a normal span of life without much disability.

Saccular (Circumscribed) Aneurysms. These are almost always caused by syphilis and are present in about 30 per cent of all cases of cardiovascular syphilis. However, syphilis may also give rise to a fusiform dilatation of the aorta. Syphilitic aneurysms are usually single, varying from a few centimeters to more than twenty in diameter. Occasionally, small daughter aneurysms project from the main mass.

SIGNS AND SYMPTOMS

Aneurysms of the aorta are remarkable in that a large aneurysm may be present and persist for several years without producing clinical manifestations. The signs and symptoms depend upon the site and size of the aneurysm The general clinical features of aneurysms will be discussed first, then the characteristics of aneurysms at different locations. In general, the clinical features include the pressure syndrome, physical signs due to mass, altered circulatory dynamics, and the rupture syndrome.

Pressure Syndrome. PAIN. Pain is the most common and earliest symptom of aneurysm of the aorta and is present in more than 60 per cent of cases. In aneurysms of the arch, pain may be felt in the retrosternal region, left side of the neck, occipital region, or back, and may radiate down the left arm or both arms In aneurysms of the descending thoracic aorta, pain is located posteriorly in the lower part of the thorax and in the loins Pain is not a feature of aneurysm of the ascending aorta until the sac erodes the bone (either sternum or ribs) The pain is usually persistent, "neuralgic" in type, or it may be intermittent and dull *The pain is markedly influenced by any change of posture*, particularly in aneurysms of the arch and descending aorta.

Pressure on Bones This produces a continuous, agonizing, and boring pain. Such a pain is produced by pressure on the ribs or sternum by aneurysms of the ascending aorta and arch, and on the spine and ribs by aneurysms of the descending aorta Pressure on the vertebrae results in destruction of their bodies while the vertebral disks remain intact (Fig. 15-134). Erosion of the ribs may occur without pain (although this is rare), and occasionally pain disappears after the erosion of a rib is complete.

Pressure on Nerves Pain due to pressure on the nerve roots is neuralgic in type. Pain in the neck is probably caused by abnormal afferent impulses reaching the cervical spinal cord as a result of distention of the transverse arch. Aneurysms of the descending aorta are more likely to press on spinal nerve roots

Coronary Pain The involvement of coronary vessels, particularly at their openings in the sinus of Valsalva, may produce pain which in character and distribution is similar to and indistinguishable from "angina pectoris"

NEUROLOGICAL MANIFESTATIONS *Left Recurrent Laryngeal Nerve* This nerve, because of its close proximity to the aortic arch, is frequently involved in aneurysms of the arch The abductor fibers are involved earlier than their adductor counterparts and therefore *the left vocal cord is, at first, in the position of adduction.* During phonation, the right vocal cord meets the left and thus the voice may remain normal. Hence, a laryngoscopic examination is necessary to detect, at an early stage, the involvement of the left recurrent laryngeal nerve, since this may be associated with even a small aneurysm. Later, as the pressure increases, adductor fibers are also damaged, and consequently the left cord remains immobile in "cadaveric position," midway between full inspiration and full expiration. It is at this stage that the patient develops *hoarseness,* which is present in about 20 per cent of patients with aneurysms of the arch Hoarseness may be the first presenting symptom. The voice may

Fig. 15-13. Aneurysm of ascending aorta, arch, and descending aorta, showing bronchiectatic changes in the lower lobe of the left lung D Aneurysm of the ascending aorta and arch of the aorta, showing fluid in the right pleural cavity E. Lateral roentgenogram showing forward displacement and narrowing of the lumen of the esophagus caused by an aneurysm of the aorta

be muffled, husky, cracked, *hoarse*, or tremulous; later, *aphonia* may supervene.

Right Recurrent Laryngeal Nerve. In rare instances the right vocal cord may be paralyzed if the aneurysm extends to the subclavian artery and presses on the right recurrent laryngeal nerve.

Phrenic Nerve. Irritation of the phrenic nerve may give rise to *hiccup* and later may (rarely) even produce *paralysis* of the left dome of the diaphragm, which is *raised*; paradoxical movements are observed on fluoroscopy.

Sympathetic Nerves. As with other nerves, pressure on sympathetic nerves first produces irritation and later paralysis During the stage of irritation, *the ipsilateral pupil is dilated* and there may be associated sweating and flushing on the same side of the face, ear, and at times the upper extremity During the stage of paralysis, *the pupil of the affected side is smaller than that of the opposite side,* there may be enophthalmos, and a slight degree of ptosis is present. These pupillary changes may also be due to differences in the blood pressure of the carotids (the pupil may be dilated on the side of the carotid with lower pressure). Syphilitic lesions of the central nervous system may also produce *inequality* of the pupils (*Argyll Robertson sign*).

Intercostal Nerves An aneurysm that presses backwards and erodes the vertebrae and posterior portions of the ribs is likely to press upon the intercostal nerves. In these cases, severe pain is felt along the course of these nerves and the overlying skin may at times become anesthetic (anesthesia dolorosa)

Vagus Nerve. Involvement of the vagus nerve may produce dyspnea, dysphagia, vomiting, and bradycardia.

PRESSURE ON RESPIRATORY PASSAGES. *Cough* and *dyspnea* are the commonest symptoms of pressure on the respiratory passages

Cough. This is present in about 60 per cent of these cases, and, in approximately one-half of them, it is the initial symptom Many types of coughs are encountered in cases of aneurysm, the specific type depends upon the underlying cause:

A *dry, rough, and irritating cough* is occasionally associated with wheezing and dyspnea. This type of cough results from pressure on the trachea and main bronchi. Such a cough may increase in intensity and become more troublesome *on exertion*, probably due to the *increase of* pressure caused by distention of the sac of the aneurysm. It tends to diminish *on rest.*

A *productive cough* is present when tracheitis, bronchitis, and bronchiectasis are caused as a result of obstruction.

A brassy and ringing cough suggests involvement of the left recurrent laryngeal nerve and results from pressure on this nerve.

Dyspnea. Dyspnea, the next most frequent symptom of pressure on the respiratory tract, is present in about 40 per cent of these cases, and may often be the initial complaint. It may be caused by (1) diminished intrathoracic space resulting from a large aneurysm, and may appear on exertion; (2) pressure on trachea or bronchus, and then be present even at rest; or (3) reflex irritation of the vagus nerves which might bring about bilateral adductor spasm of vocal cords followed by dyspnea and *stridor*. (4) Occasional paroxysms may be secondary to left ventricular failure resulting from hypertension, aortic insufficiency, or coronary heart disease, and there may be nocturnal dyspnea caused by pressure of the aneurysm on the trachea or bronchus when the patient is in the supine position

PRESSURE ON A BRONCHUS. This causes *pulmonary change* If the pressure is gradual, overdistention of the lung occurs, resulting in emphysema, which occasionally may be mistaken for pneumothorax. Complete obstruction results in atelectasis of the involved lung (Fig. 15-13B), followed by pneumonitis, bronchiectasis (Fig 15-13C), and even fibrosis. This may simulate pulmonary tuberculosis and has therefore been called "aneurysmal phthisis" Atelectasis may involve one or more lobes and is more extensive when the aneurysm involves the descending aorta. Pleural irritation caused by aneurysm of the aorta may give rise to pleural effusion (Fig 15-13D).

PRESSURE ON THE ESOPHAGUS *Dysphagia* is an uncommon manifestation of aneurysm of the aortic arch, but more frequently accompanies aneurysms of the descending aorta. Dysphagia may be caused by various factors:

1 Esophageal spasm resulting from irritation of the left recurrent laryngeal nerve This may occur in the early stages of aneurysm and is transient.

2 Partial obstruction of the esophagus due to compression (Fig 15-13D). This type of dysphagia is usually constant

3 Pain on swallowing, which may be caused by ulceration of the esophagus as a result of pressure

PRESSURE ON BLOOD VESSELS AND HEART. *Superior Vena Cava.* Pressure on the superior vena cava is common in aneurysms of the ascending aorta It produces edema and cyanosis of the head, neck, face, and upper extremities. The superficial veins of the thorax and upper abdomen become dilated and tortuous and fill abnormally in the cephalocaudal direction on the thorax, the reverse being normally true Edema of the right upper half of the chest may at times be produced by unilateral pressure

Pulmonary Artery. This artery may be compressed by an aneurysm of the ascending aorta or aortic arch, giving rise to a clinical picture of *cor pulmonale*

Other Arteries Compression of one or more arteries may lead to *unilateral or bilateral disappearance of the pulse* It might also produce a *delay* in the appearance of the pulse wave, thus the left pulse will be felt later than the right if the aneurysm is located between the origins of the right innominate and left subclavian arteries When *the pulses are markedly unequal*, the blood pressure is also diminished on the side of the feeble pulse A difference of more than 30 mm in the systolic pressure of the upper extremities is highly suggestive of aneurysm.

Veins Compression of large venous channels, e g, the innominate and azygos veins, may occur, producing congestion in the areas drained

Heart The heart is displaced *downward and to the left* in aneurysms of the ascending aorta An aneurysm of the descending thoracic aorta may displace the heart *upwards and to the right*, and pulsation in the epigastric region would then be the presenting sign of the aneurysm.

Physical Signs Due to the Mass. An aneurysm which expands outwards is likely to produce a round expansile mass with a *systolic thrill* A *diastolic shock* may occasionally be present due to the recoil of the blood in the aneurysm The apical impulse might be displaced as already described. There may be a *double pulsation*, the systolic impulse being followed by a diastolic thrust, caused by the recoil of retrocardiac aneurysm (*Hope's sign*).

In cases of aneurysm of the ascending aorta, an area of *dullness* may be detected in the 2d right intercostal space, in the retrosternal area, or below the clavicle. In cases of large aneurysms, *a systolic murmur* is usually present. A *double murmur*, systolic and diastolic, may also be audible, and this may be caused by the blood entering and leaving the aneurysmal sac through a narrow opening. However, in the presence of a diastolic murmur, aortic regurgitation should also be considered. Accentuation of the *aortic 2d sound* is a sign suggestive of aortic aneurysm, but it also occurs per se in syphilitic aortitis

Changes in Circulatory Dynamics. As long as the aneurysmal sac contains fluid blood, it behaves like a large and elastic *reservoir of blood.* As this sac fills during systole, it has a damping effect, and this reduces the systolic pressure and increases the diastolic pressure, bringing it nearer the mean pressure. Hence, the pulse of an artery which takes its origin below the aneurysm will be comparatively feeble and have a slower rise (*pulsus tardus*).

Pulsus tardus always gives the impression of a delayed pulse because the palpating finger feels the peak of the wave and not the onset of the rise, but a real delay may be present. Exact details of the changes in circulatory dynamics are better revealed by pulse tracings.

Some aneurysms with inelastic sacs may behave differently and may rarely increase the amplitude of the pulse distal to the sac.

Although 15 to 30 per cent of aneurysms may be asymptomatic, in *general the important* symptoms of aneurysm are pain, cough, dyspnea, hoarseness, hemoptysis, and dysphagia. The pressure signs and symptoms depend upon the structures compressed

Rupture Syndrome. PERICARDIUM Rupture of an aneurysm of the ascending aorta may occur in the *pericardium*, thus producing *sudden cardiac tamponade* usually resulting in death.

PLEURA AND LUNGS. An aneurysm of the thoracic aorta may rupture into the pleural cavity or a lung. Thus, a sudden fatal *hemothorax* or repeated bouts of *hemoptysis* could occur from the involvement of lung tissue

TRACHEA AND BRONCHI. In *general*, *aneurysms* of the ascending aorta rupture into the

right bronchus, whereas aneurysms of the arch or descending aorta rupture into the left bronchus. Involvement of the trachea is likely to occur in aneurysm of the ascending aorta. *Initially the leak is small and only streaks of blood are coughed up, but often the hemoptysis is profuse and fatal.*

ESOPHAGUS Rupture into the esophagus may occur in aneurysm either of the arch or of the descending aorta. The oozing of blood may be a forerunner of final rupture. Small amounts of blood are frequently vomited; or occult blood is detected in the stools. Because of the vulnerability of these aneurysms, an esophagoscope should be used with great caution, or not at all, on patients who complain of dysphagia

SUPERIOR VENA CAVA. An aneurysm of the ascending aorta may rupture into the superior vena cava The symptoms start suddenly. The face of the patient becomes swollen, cyanotic, and suffused, giving the appearance of strangulation. Other manifestations of superior vena cava syndrome also develop A *continuous thrill and murmur* are detectable in the 1st and 2d right intercostal spaces anteriorly. Congestive failure, with edema of the lower extremities, may develop and the liver may become markedly distended, showing systolic *pulsations* However, the most typical picture is that of cyanosis and edema in the upper part of the body.

INFERIOR VENA CAVA An aneurysm of the *abdominal* aorta may rupture into the inferior vena cava. This leads to sudden appearance of *edema and cyanosis* of the lower extremities, and rectal bleeding *may be present* There may be a *continuous murmur* at the site of rupture. There usually is *evidence of high output failure* with collapsing pulse.

PULMONARY ARTERY. The patient is suddenly seized by an attack of marked dyspnea, and a sense of tightness and fullness *in the chest* *Shock* may supervene, precipitating death, but some patients recover and may live for several months or longer Dyspnea is severe, continuous, and out of proportion to the few *moist* sounds present in the chest The intensity of the dyspnea is probably due to sudden pulmonary congestion. A *continuous thrill and a harsh continuous murmur* are present at the base of the heart, chiefly in the 2d, 3d, and 4th left intercostal spaces, 1 to 3 cm to the left of the sternum. Peripheral signs of wide pulse pressure are manifest, while cyanosis is absent or minimal.

RIGHT ATRIUM OR RIGHT VENTRICLE. Clinical manifestations are similar to those which follow the rupture of an aneurysm of the sinus of Valsalva into the right atrium or right ventricle (see below).

EXTERNAL RUPTURE. Aneurysms of the ascending aorta rarely rupture through the skin. After perforating through the ribs and sternum, an aneurysm may be present as *a mass*, with stretched overlying skin Rupture through the skin is uncommon.

MEDIASTINUM. Rupture into the mediastinum is also very rare.

LOCATIONS

Aneurysms of the Sinus of Valsalva. These are rare and usually due to congenital dilatation, but may be caused by syphilis or bacterial endocarditis.

RIGHT SINUS. As seen on roentgenography or fluoroscopy, an aneurysm in this location produces a round shadow which projects forward and upward to the right, and rests at the root of the aorta on a small base. It often shows intrinsic pulsations as well as mural calcification and may erode the bony structures It may compress the right ventricle and rupture into the right ventricle or atrium, resulting in an aortocardiac fistula. This gives a *continuous machinery murmur* heard behind the sternum It may rupture into the pericardium, resulting in *hemopericardium* and cardiac tamponade.

LEFT SINUS Aneurysms in this location may compress the pulmonary artery and produce cor pulmonale. Rupture of the aneurysm into the pulmonary artery will produce a continuous murmur and simulate patent ductus arteriosus

POSTERIOR SINUS Aneurysms here may rupture into the left atrium and produce an aortocardiac shunt. Aneurysms of the left and posterior sinus of Valsalva frequently escape detection during life because of their position

The Ascending Aorta. The ascending aorta extends upward from the sinus of Valsalva for 5 cm, to a portion just below the innominate artery, its entire course is intrapericardial This is a frequent site for aortic aneurysms Symptoms of aneurysm at this site may be *minimal* even when the aneurysm *is quite* large This is why the early writers (Broad-

bent) called this an "aneurysm of physical signs" The aneurysm may develop towards the right or the left. In those which develop to *the right*, the symptoms may be severe or absent, depending upon the size of the aneurysm The sac develops from the convex surface anteriorly and to the right, giving rise to an *expansile pulsating mass* in the 2d, 3d, or 4th right or left intercostal spaces, or behind the manubrium The pulsation is systolic and often heaving There is associated dullness over the area corresponding to the aneurysm. There may be *a systolic or a diastolic murmur* and quite often a *tracheal tug* is present when the aneurysm extends to the arch of the aorta. The radial pulses are equal If the aneurysm is large, the heart may be displaced to the left Pulsations in the aneurysm will be minimal if it is filled by a thrombus *Cardiac dyspnea* may be present if the patient has left ventricular failure due to aortic incompetence *Precordial pain*, often transmitted to the right arm, *may be felt*. This may be a constant sense of dull retrosternal pain or pressure, which often increases on exertion The electrocardiogram may reveal evidence of left axis deviation, depending upon a frequent coexistence of left ventricular hypertrophy Fluoroscopy may reveal a slight bulge on the right border of the heart at the junction of aorta and right atrium

Aneurysms developing *to the left of the aorta* produce a greater increase in the transverse diameter at the base of the heart and frequently evoke manifestations of right ventricular failure by pressing on the pulmonary artery (*cor pulmonale*) A pulsatile bulge may be present in the 2d, 3d, or 4th left intercostal space The left upper border of the cardiac silhouette appears deformed on fluoroscopy.

The following structures may also be compressed and produce syndromes which have been already discussed right bronchus, lung, and pleura, superior vena cava; pulmonary artery, ribs (with subsequent erosion), sternoclavicular joint.

The pressure manifestations may be progressive and may terminate in rupture of the aneurysm in any of the following sites. pericardium, right bronchus, pleural cavity and lung, pulmonary artery, superior vena cava, or cardiac chambers, or it may rupture outwards. The clinical picture resulting from rupture at each of the sites listed has been already described.

The Arch of the Aorta. Aneurysm of the arch has been called "aneurysm of symptoms" (Broadbent) because its anatomical situation and relation to other organs are such that even a small aneurysm can produce symptoms of compression.

Posteriad to the arch of the aorta lie the trachea, esophagus, sympathetic plexus, and thoracic duct; inferiad, the left bronchus; anteriad, the left phrenic and left recurrent laryngeal nerves. It may come in contact with intercostal nerves or the brachial plexus Pressure on any or all of these structures results in a *compression syndrome*, the manifestations of which have been discussed.

Physical examination may reveal an *abnormal pulsation* at the suprasternal notch or the supraclavicular regions, or both The pulsatile mass may lift the manubrium and later may bulge out (Fig. 15-14A). It is covered by stretched skin, and at times blood may ooze out Though rupture often appears to be imminent, it is uncommon.

Percussion of the manubrium reveals dullness if the aneurysm is large. A rare manifestation is *clubbing of the fingers* on the affected side.

TRACHEAL TUG Owing to the pressure of the aneurysm on the left bronchus, the larynx is drawn downward (*Oliver's sign*) or to the left (*Cardarelli's sign*) with each cardiac pulsation (tracheal tug) If tug is present, it is highly suggestive of an aneurysm of the aortic arch and thus is of help in excluding other mediastinal growths.

The best method of detecting this sign is as follows The patient is kept in an erect position and directed to close his mouth and elevate his chin, thereby stretching the trachea The cricoid cartilage is then grasped between the examiner's index finger and thumb (or palpated by placing the index finger over the Adam's apple) and a gentle and steady upward pressure is applied. If the cricoid cartilage is drawn caudally with each ventricular contraction, then tracheal tug is present. Care must be taken that the fingers are not over the carotid arteries otherwise the transmitted carotid pulsations might mislead the observer

Last Part of the Arch. In this location, the aneurysmal mass projects backward and can

right bronchus, whereas aneurysms of the arch or descending aorta rupture into the left bronchus. Involvement of the trachea is likely to occur in aneurysm of the ascending aorta. Initially the leak is small and only streaks of blood are coughed up, but often the hemoptysis is profuse and fatal.

ESOPHAGUS. Rupture into the esophagus may occur in aneurysm either of the arch or of the descending aorta. The oozing of blood may be a forerunner of final rupture. Small amounts of blood are frequently vomited; or occult blood is detected in the stools. Because of the vulnerability of these aneurysms, an esophagoscope should be used with great caution, or not at all, on patients who complain of dysphagia.

SUPERIOR VENA CAVA. An aneurysm of the ascending aorta may rupture into the superior vena cava. The symptoms start suddenly. The face of the patient becomes swollen, cyanotic, and suffused, giving the appearance of strangulation. Other manifestations of superior vena cava syndrome also develop. A *continuous thrill and murmur are detectable in the 1st and 2d right intercostal spaces anteriorly*. Congestive failure, with edema of the lower extremities, may develop and the liver may become markedly distended, showing systolic pulsations. However, the most typical picture is that of cyanosis and edema in the upper part of the body.

INFERIOR VENA CAVA. An aneurysm of the abdominal aorta may rupture into the inferior vena cava. This leads to sudden appearance of edema and cyanosis of the lower extremities, and rectal bleeding may be present. There may be a *continuous murmur* at the site of rupture. There usually is evidence of *high output failure* with collapsing pulse.

PULMONARY ARTERY. The patient is suddenly seized by an attack of marked dyspnea, and a *sense of tightness and fullness in the chest*. *Shock* may supervene, precipitating death, but some patients recover and may live for several months or longer. Dyspnea is severe, continuous, and out of proportion to the few moist sounds present in the chest. The intensity of the dyspnea is probably due to sudden pulmonary congestion. *A continuous thrill and a harsh continuous murmur* are present at the base of the heart, chiefly in the 2d, 3d, and 4th left intercostal spaces, 1 to 3 cm to the left of the sternum. Peripheral signs of wide pulse pressure are manifest, while cyanosis is absent or minimal.

RIGHT ATRIUM OR RIGHT VENTRICLE. Clinical manifestations are similar to those which follow the rupture of an aneurysm of the sinus of Valsalva into the right atrium or right ventricle (see below).

EXTERNAL RUPTURE. Aneurysms of the ascending aorta rarely rupture through the skin. After perforating through the ribs and sternum, an aneurysm may be present as *a mass*, with stretched overlying skin. Rupture through the skin is uncommon.

MEDIASTINUM. Rupture into the mediastinum is also very rare.

LOCATIONS

Aneurysms of the Sinus of Valsalva. These are rare and usually due to congenital dilatation, but may be caused by syphilis or bacterial endocarditis.

RIGHT SINUS. As seen on roentgenography or fluoroscopy, an aneurysm in this location produces *a round shadow* which projects forward and upward to the right, and rests at the root of the aorta on a small base. It often shows intrinsic pulsations as well as mural calcification and may erode the bony structures. It may compress the right ventricle and rupture into the right ventricle or atrium, resulting in an aortocardiac fistula. This gives a *continuous machinery murmur* heard behind the sternum. It may rupture into the pericardium, resulting in *hemopericardium* and cardiac tamponade.

LEFT SINUS. Aneurysms in this location may compress the pulmonary artery and produce cor pulmonale. Rupture of the aneurysm into the pulmonary artery will produce a continuous murmur and simulate patent ductus arteriosus.

POSTERIOR SINUS. Aneurysms here may rupture into the left atrium and produce an aortocardiac shunt. Aneurysms of the left and posterior sinus of Valsalva frequently escape detection during life because of their position.

The Ascending Aorta. The ascending aorta extends upward from the sinus of Valsalva for 5 cm. to a portion just below the innominate artery. Its entire course is intrapericardial. This is a frequent site for aortic aneurysms. Symptoms of aneurysm at this site may be minimal even when the aneurysm is quite large. This is why the early writers (Broad-

bent) called this an "aneurysm of physical signs" The aneurysm may develop towards the right or the left. In those which develop *to the right*, the symptoms may be severe or absent, depending upon the size of the aneurysm The sac develops from the convex surface anteriorly and to the right, giving rise to an *expansile pulsating mass* in the 2d, 3d, or 4th right or left intercostal spaces, or behind the manubrium. The pulsation is systolic and often heaving. There is associated dullness over the area corresponding to the aneurysm. There may be *a systolic or a diastolic murmur* and quite often a *tracheal tug* is present when the aneurysm extends to the arch of the aorta. The radial pulses are equal If the aneurysm is large, the heart may be displaced to the left Pulsations in the aneurysm will be minimal if it is filled by a thrombus. *Cardiac dyspnea* may be present if the patient has left ventricular failure due to aortic incompetence *Precordial pain*, often transmitted to the right arm, may be felt. This may be a constant sense of dull retrosternal pain or pressure, which often increases on exertion The electrocardiogram may reveal evidence of left axis deviation, depending upon a frequent coexistence of left ventricular hypertrophy Fluoroscopy may reveal a slight bulge on the right border of the heart at the junction of aorta and right atrium

Aneurysms developing *to the left of the aorta* produce a greater increase in the transverse diameter at the base of the heart and frequently evoke manifestations of right ventricular failure by pressing on the pulmonary artery (*cor pulmonale*) A pulsatile bulge may be present in the 2d, 3d, or 4th left intercostal space The left upper border of the cardiac silhouette appears deformed on fluoroscopy

The following structures may also be compressed and produce syndromes which have been already discussed right bronchus, lung, and pleura, superior vena cava, pulmonary artery, ribs (with subsequent erosion), sternoclavicular joint

The pressure manifestations may be progressive and may terminate in rupture of the aneurysm in any of the following sites pericardium, right bronchus, pleural cavity and lung, pulmonary artery, superior vena cava, or cardiac chambers, or it may rupture outwards The clinical picture resulting from rupture at each of the sites listed has been already described.

The Arch of the Aorta. Aneurysm of the arch has been called "aneurysm of symptoms" (Broadbent) because its anatomical situation and relation to other organs are such that even a small aneurysm can produce symptoms of compression.

Posteriad to the arch of the aorta lie the trachea, esophagus, sympathetic plexus, and thoracic duct; inferiad, the left bronchus, anteriad, the left phrenic and left recurrent laryngeal nerves. It may come in contact with intercostal nerves or the brachial plexus. Pressure on any or all of these structures results in a *compression syndrome*, the manifestations of which have been discussed

Physical examination may reveal an *abnormal pulsation* at the suprasternal notch or the supraclavicular regions, or both *The pulsatile* mass may lift the manubrium and later may bulge out (Fig 15-14A). *It is* covered by stretched skin, and at times blood may ooze out. Though rupture often appears to be imminent, it is uncommon.

Percussion of the manubrium reveals dullness if the aneurysm is large. A rare manifestation is *clubbing of the fingers* on the affected side.

TRACHEAL TUG Owing to the pressure of the aneurysm on the left bronchus, the larynx is drawn downward (*Oliver's sign*) or to the left (*Cardarelli's sign*) with each cardiac pulsation (tracheal tug). If tug is present, it is highly suggestive of an aneurysm of the aortic arch and thus is of help in excluding other mediastinal growths.

The best method of detecting this sign is as follows The patient is kept in an erect position and directed to close his mouth and elevate his chin, thereby stretching the trachea The cricoid cartilage is then grasped between the examiner's index finger and thumb (or palpated by placing the index finger over the Adam's apple) and a gentle and steady upward pressure is applied. If the cricoid cartilage is drawn caudally with each ventricular contraction, then tracheal tug is present. Care must be taken that the fingers are not over the carotid arteries otherwise the transmitted carotid pulsations might mislead the observer.

Last Part of the Arch. In this location, the aneurysmal mass projects backward and can

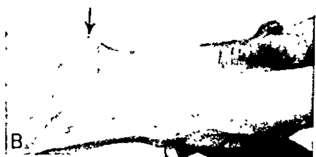

Fig. 15-14. A. Aneurysm of the aortic arch, showing prominent bulge in the region of the manubrium. B. Aneurysm of the abdominal aorta, showing a prominent mass in the epigastric region, as seen in a lateral view.

produce erosion of the second to fourth dorsal vertebrae causing *severe pain* and, infrequently, compression of the spinal cord and consequent *paraplegia*. Among the rarer symptoms, *dysphagia* is the most common. At times, the aneurysm may appear as a bulge between the scapulas and the spine and may attain quite a large size.

The Descending Thoracic Aorta. The thoracic aorta begins at the lower border of the fourth thoracic vertebra, lies in the posterior mediastinum, and extends down to the aortic hiatus, which is located at the lower border of the twelfth thoracic vertebra An aneurysm in this location develops insidiously and is likely to be overlooked till it produces manifestations of compression. *Pain*, the most common symptom, results from pressure on the spine and may be present for 10 to 15 years The site and character of the pain have already been discussed. *Dysphagia, hemoptysis,* and *hematemesis,* though uncommon, are more frequently present with aneurysms in this location than those elsewhere The patient may die suddenly, or present profuse hematemesis for the first time; alternatively the blood may move along the gastrointestinal tract The *clinical picture* depends upon the structures compressed, particularly the left bronchus, left pleura and lung, vertebrae, ribs, spinal cord, and esophagus. *Physical signs* may be conspicuous by their absence, even when the aneurysm assumes large dimensions. However, abnormal dullness on percussion and a systolic pulsation may be observed below the angle of the left scapula or in left interscapular space. When the posterior ribs are eroded, a pulsating mass is seen in the back and, infrequently, when such a mass projects forward an abnormal epigastric pulsation may be present, due to forward displacement of the heart. The femoral pulse may be smaller and delayed as compared to the radial.

DIAGNOSIS Calcification of an aortic aneurysm in this location is frequent and is usually located 1 to 3 mm within the outer border of the aneurysmal shadow; it often extends for a long distance. *Angiocardiography* or *aortography* is of great value in helping to visualize the aorta and, unless the aneurysm is clotted, either one will demarcate the boundaries of the aneurysm.

PROGNOSIS. Fifty per cent of patients with syphilitic aneurysm die because of rupture of the aneurysm. In patients with aneurysm and aortic insufficiency, heart failure accounts for one-third of the deaths Intercurrent infection and asphyxia are responsible for death in some cases About 60 per cent die within 12 months after the appearance of the first symptom Aneurysms of the aortic arch are particularly serious

DIFFERENTIAL DIAGNOSIS Various lesions of the mediastinum may simulate aneurysms very closely Important among them are tumors, e g , carcinoma of the bronchus, thymic tumors, intrathoracic goiter, neurofibroma, lymphoblastoma, and sarcoidosis Some types of cysts, such as dermoid, pericardial, coelomic, and lymphatic, may present diagnostic problems.

A tubercular abscess of the spine and a diaphragmatic hernia will also have to be excluded.

Fluoroscopy will help to determine whether the mass can be separated from the aortic shadow Ingestion of a thin barium suspension will differentiate between intrinsic lesions of the esophagus and compression from outside. Barium studies in the Trendelenburg position will help to exclude a diaphragmatic hernia. It is important to determine whether the shadow lies in the anterior or posterior mediastinum In the anterior mediastinum, a dermoid cyst, a teratoma, a lymphoma, or a lymphangioma is more usual, while tumors of neurogenic origin are located in the posterior mediastinum A dermoid cyst is usually a solitary, round, homogenous opacity in the anterior mediastinum It is sometimes calcified Teratomas often are irregular in density and may contain teeth or bones Lymphatic cysts are generally located in the posterior mediastinum and may be single or multiple A lymphoblastoma will shrink with x-ray radiation

The Abdominal Aorta. Till a decade or two ago, all the aneurysms of the abdominal aorta were considered to be of luetic origin. It is now realized that most of these aneurysms are caused by arteriosclerosis instead

INCIDENCE AND CAUSE Formerly thoracic aneurysms were thought to be seven to ten times more common than abdominal Recently, however, the proportion has declined to 4.1 Current statistics also reflect upon the decline in the luetic origin of these aneurysms and a corresponding increase in atherosclerotic aneurysms

Mamgha et al (1952) found that the ratio of arteriosclerotic to syphilitic aortic aneurysms was 1 10 for each 1,000 autopsies performed during the years 1932–1935 and 1 1 4 in 1940–1948 The ratio decreased thereafter to 1·0 4 (or 2 5 1) in the subsequent group of 1,000 autopsies analyzed for the years 1949–1951.

In the analysis of abdominal aneurysms, 96 per cent were arteriosclerotic and 4 per cent were syphilitic Similarly, in Blackmoore's series (1954) of 124 cases of abdominal aneurysm, 10 were attributed to syphilis Mills and Horton (1938) reported 8.8 per cent of abdominal aneurysms were due to syphilis Atherosclerosis was the cause of 97 out of 102 cases of abdominal aneurysm in the series reported by Estes Congenital defects; abdominal wounds, including gunshot injury; inflammatory vascular lesions due to tuberculosis; streptococcal infection; and rheumatic fever are among the rare causative factors Abdominal aneurysms occur more frequently in men, the ratio being about 5:1. Syphilitic aneurysms usually occur between the fourth and fifth decades, while those of arteriosclerotic origin occur in the sixth and seventh decades.

ASSOCIATED DISEASES Severe coronary arteriosclerosis with myocardial infarction was noted in 16 out of 21 autopsied cases. Angina pectoris, cerebrovascular diseases, pulmonary tuberculosis, and kidney diseases may also be associated with abdominal aneurysm.

SIGNS AND SYMPTOMS. *Aneurysms of the abdominal aorta may be asymptomatic in about one-third of the cases. Syphilitic aneurysms of the abdominal aorta produce symptoms early, arteriosclerotic ones, on the other hand, due to their more anterior location, either are entirely asymptomatic or produce symptoms only at a late stage. Below are the common manifestations, depending upon the location and the size of the aneurysms.

Pain Pain is the commonest symptom, but may be absent in 20 to 50 per cent of cases It may be caused by vertebral erosion, pressure on dorsal nerve roots, hemorrhage into the perirenal space, displacement of a kidney, or ureteric obstruction It is frequently felt in the lumbar region and is paroxysmal at onset, but later becomes constant and boring, throbbing, or cutting The site and radiation of the pain depend upon the location of the aneurysm If the aneurysm involves the upper part of the abdominal aorta, pain may be felt at the epigastrium and may extend over the entire abdomen. If it is located in the lower part of the abdomen, the pain radiates to the lumbar region and may (at times) simulate renal colic in about 20 per cent of the cases It may also radiate down the posterior aspect of the thighs. Root pain radiating from the back to the upper abdomen can also be produced Pain may be so severe as to require opiates It may be modified by change of posture

Pressure Pressure on the spinal cord may give rise to a clinical picture of compression myelitis Pressure on the abdominal viscera,

e.g., pylorus and duodenum, may lead to nausea and vomiting. There may be episodes, simulating paralytic ileus, caused by mechanical compression of the intestine or lesions of the mesenteric arteries. Pressure on the kidney and ureter may produce hydronephrosis.

Pulsation. Some patients are aware of pulsations and may consult a physician about them. Pulsation may occasionally be described by the patient as a throbbing pain, but pulsation and pain may be felt independently of each other.

Physical Signs. The mass is the outstanding physical finding and may be present in the lower epigastric (Fig 15-14B) umbilical, or left hypochondriac regions. In most cases, the mass is pulsatile (*expansile pulsation*) and, in some, it may reveal progressive enlargement. It is worthwhile to emphasize that a pulsating aorta is not diagnostic, because such pulsations may be observed in asthenic individuals with an exaggerated lumbar curve. Neurotic, thin women, particularly, become more conscious of these pulsations. It also must be stressed that the patient should be put in a knee-elbow position to permit the examiner to decide whether the pulsation is from the aneurysm or transmitted from the aorta A *systolic murmur* and a *thrill* have been recorded in only a few cases but this may be partly due to inadequate search for these signs or to intraluminal clotting. The *pulse of the femoral artery may be retarded* and the systolic blood pressure of the femoral artery may be equal to or less than that of the brachial arteries, the reverse being the case normally. However, the diastolic blood pressure may be higher, tending to be nearer the mean pressure. Tenderness is present in about 50 per cent of patients with abdominal aneurysms Although about one-third of the cases may be asymptomatic, the important manifestations of abdominal aneurysm are pain, presence of a pulsating mass in the abdomen, and gastrointestinal disturbances

COURSE AND COMPLICATIONS. An aneurysm of the abdominal aorta may persist for years without causing serious disturbances However, rupture of the aorta, retroperitoneal oozing, obliteration of the lumen by clots (so complete at times as to lead to death), paraplegia from compression of the cord, and obstruction of the superior mesenteric artery, may result

Rupture of the Aorta. This is the chief possible complication. Though an intact aorta can withstand a pressure of 1,000 to 3,000 mm Hg before bursting, an arteriosclerotic aorta may yield to mild hypertension or even normal pressure. Rupture of the aorta is an acute, catastrophic event accompanied by severe pain, in the abdomen or back, which may radiate to the groins or legs. The pain may be of unusual severity, and is described as "agonizing," "piercing," or "tearing;" it is probably not due to the perforation, but to the tearing of retroperitoneal tissues by the blood. Unusual *pallor* may occur early, even before the onset of *shock* which supervenes after a few minutes and may last for hours Some patients *lose consciousness* and die during this stage, but others may survive for a few hours, the so-called "lucid interval." Signs of a gradually increasing retroperitoneal hematoma develop, and paralytic ileus may appear in 5 to 24 hr, with severe distention, vomiting, and hiccup Deaths due to aneurysmal rupture have hitherto been overestimated because these form the bulk of the cases of abdominal aneurysm which are seen at autopsy. *Rupture probably occurs in about 50 per cent of the cases.* An abdominal aneurysm is most likely to rupture into the retroperitoneal space or the peritoneal cavity, and infrequently into the gastrointestinal tract. At times, it may rupture into the inferior vena cava, but rupture through the skin is rare. However, this gloomy picture is changing due to the spectacular results reported by the application of modern surgical techniques Surgical mortality has been said to vary from 10 to 60 per cent. Patients have been operated upon successfully even after rupture. However, it is very important to obtain a correct diagnosis as early as possible.

Retroperitoneal Oozing. Extravasation of blood may precede a major and fatal rupture. This could give rise to new and more severe pains radiating to hips and legs These symptoms may antedate rupture by a few days The retroperitoneal hematomas so produced may assume large dimensions, producing ecchymosis over the lumbar, inguinal, iliac, and scrotal regions and obliterate the psoas muscle shadow on radiography. About 60 to 80 per cent of patients with this difficulty die, but in a rare case there may be survival for long periods

DIAGNOSIS *Roentgenography* is helpful in arriving at the diagnosis of an abdominal aneurysm A *soft shadow* caused by the aneurysm or a large aorta is present in over 50 per cent

of the cases. The most common finding, present in over 70 per cent of the cases, is that of scattered plaques of calcification in the wall of the aneurysm or in the aorta. *Displacement* of neighboring structures or a soft tissue mass may give a hint. Insufflation of colon and stomach with gas, or visualization with a barium meal and descending pyelography, are at times employed to demonstrate displacement and to exclude abnormalities of gastrointestinal and urinary tracts. *Vertebral erosion* is present in a small percentage of cases and occasionally the erosion may involve the ribs at the costovertebral angles Erosion of the spine can be best visualized in the 45° left lateral position With *aortography*, diagnosis can be made with certainty in most of the cases It usually shows a wide lumen of the aneurysm but, at times, the lumen seems relatively normal due to the presence of clots The chief value of aortography lies in (1) determining the extent of aneurysm, particularly with reference to its proximity to renal arteries, (2) visualizing the irregularity of lumen, and (3) demonstrating a normal aorta in a suspected case of abdominal aneurysm *Progressive leucocytosis and anemia*, when associated with fever in the presence of abdominal aneurysm, is highly suggestive of a leaking aneurysm.

PROGNOSIS. In the series reported by Estes, of 102 cases 96 per cent were arteriosclerotic, 1 per cent syphilitic, and rest had a combined causation Only 18 9 per cent of the patients in the series were alive at the end of 5 years In the series reported by Cranley et al, two-thirds of the patients were dead within 3 months after the appearance of symptoms As the mortality resulting from aortic aneurysms is high, the control of aneurysms would add to the longevity of these patients.

DIFFERENTIAL DIAGNOSIS *Correct* clinical diagnosis, confirmed at autopsy or laparatomy, has hitherto been possible in only one-third to one-half of the cases Common conditions which must be excluded include those described below

Renal Disorders The pain produced by abdominal aneurysm has many of the characteristics of renal pain, and therefore is confused with that of nephrolithiasis, perinephric abscess, hypernephroma, hydronephrosis, prostatic urinary obstruction, and pyelonephritis, the pain is rarely relieved by antispasmodics and opiates. These clinical conditions, on the other hand, may simulate an aneurysm. However, infrequently, there is actual involvement of a ureter by an aneurysmal mass A urologic abnormality which cannot be explained should, therefore, lead one to suspect an abdominal aneurysm.

Pancreatic Cysts These may simulate abdominal aneurysm by transmitting the vascular pulsation. Both lesions may displace the stomach anteriorly and show calcification on a roentgenogram.

Intraabdominal Tumors. Tumors, e.g., gastric carcinomas, masses of retroperitoneal lymph nodes, sarcomas, omental tumors, and renal tumors may simulate an aneurysm, especially if they are adjacent to the aorta. Pulsatile tumors, e.g., vascular hypernephromas and tumors of the liver should also be differentiated from aneurysms.

An abdominal mass which shows expansile *pulsations is almost* pathognomonic of an abdominal aneurysm. Tenderness, characteristic of aneurysms, is not associated with the buckling of an arteriosclerotic aorta

TREATMENT

Medical. In the past, rest has been advocated in the expectation that it would induce clotting *Calcium gluconate* also was given for the same purpose. Venesection was performed to reduce the blood pressure, so as to bring about clotting in the aneurysm Potassium iodide is believed by some to relieve pain *Medical treatment of aneurysms of the aorta is unlikely to influence the prognosis.* However, if hypertension is present, limiting physical activity and lowering the blood pressure

cyanosis, and cough, when present, should be treated symptomatically If respiratory stridor is a distressing feature, chloroform inhalation may be useful. In some cases, tracheotomy or intubation of the larynx proves necessary. Complicating congestive cardiac failure and coronary heart disease should receive appropriate treatment.

Surgical (see also Chap. 8). Wiring, acupuncture, galvanopuncture, injection of gelatin into the mass, and production of an arteriovenous fistula have been tried in the past with unsatisfactory results and hence have been abandoned by most surgeons. *Wrapping of the aneurysm in strips of cellophane to bring about periaortic fibrosis has not been too satisfactory. Partial ligation of the aorta* above the aneurysm is of doubtful value. In syphilitic aneurysms the wall of the aorta is generally

firm enough to permit the placement of hemostatic sutures, whereas this is often not possible in arteriosclerotic aneurysms. At present, the treatment of choice in aortic aneurysms, atherosclerotic or syphilitic, is *excision of the aneurysm with graft replacement, if necessary.* The major problem is occlusion of the aorta during the graft replacement. The aorta can be occluded *below* the renal arteries for periods of about an hour, and this is generally adequate for the necessary graft replacement. *Above* the level of the renal arteries, occluding the aorta for more than 20 min at a time is associated with considerable risk. This can be overcome by using one of the following techniques temporary polyethylene shunts; external shunt of large caliber; hypothermia; bypassing the arch of the aorta with the aid of a pump, or using a temporary heterologous shunt between the ascending and the abdominal aorta.

8

Surgical treatment of aneurysms of the aorta

HUSHANG JAVID AND ORMAND C. JULIAN

HISTORY

Interest in the treatment of arterial aneurysm began with Antyllus, a Greek physician who lived in the first century His writings have been lost but their content was preserved by Oribasius, about A D. 350 Antyllus ligated the involved artery proximal and distal to the aneurysm According to a translation quoted by Mahorner, he noted that the operation was dangerous because the ligature could become displaced Though this method of treatment was repeatedly rediscovered and used through the years, notably by John Hunter in treating popliteal aneurysms, it did not contribute to the treatment of aortic aneurysms

A British surgeon named Moore (1864) sought to stimulate thrombosis of aneurysms of the aorta *by threading a long coil of wire into the sac* This method occasionally seemed to be productive of the desired thrombosis, and the principle was reapplied for many years The most recent proponent of this method was Blakemore, who used it until resectional methods of surgery became established This form of treatment could be successful only in *saccular aneurysms* because these are the only ones in which inactivation of the aneurysm cavity is possible and desirable Misuse in fusiform aneurysms was frequent because of a lack of understanding of the pathologic anatomy involved

Dubost et al (1952) resected a large abdominal aneurysm and bridged the defect produced in the aorta with a homologous artery graft. During the interval betwen the performance of this operation by Dubost and its publication, the same type of treatment was applied by Schafer, DeBakey (1955c), and the authors Schafer considered that interruption of blood flow in the infrarenal aorta would be intolerable and added a technique of bridging the site of surgery with a polyethylene tube during the period of occlusion Dubost, DeBakey, and the authors evaluated the situation differently and simply cross-clamped the aorta below the *renal arteries* without producing damage to the temporarily ischemic tissues

Vascular anastomosis and precedent for the implantation of a homologous vascular graft had already been provided. Significant in the development of blood vessel anastomosis was the work of Eck (1879), who first accomplished the union of two blood vessels when he made an anastomosis between the portal vein and the vena cava in the dog Carrel standardized arterial suture technique and provided a firm theoretical and technical foundation for the transplantation of vessels

The most encouraging work in vessel transplantation prior to its use in treating aneurysms was that of Gross (1948), who resected a long coarctation of the thoracic aorta in a young patient and successfully replaced it by a homologous graft. Swan (1950) resected a segment of aorta in a case of coarctation associated with aneurysm and restored the aortic continuity with the graft.

Between 1950 and 1957, surgery of the aorta made rapid progress, and many new problems arising from the extension of this field have been successfully solved. The problem of temporary occlusion of the abdominal aorta was solved when it was proved that occlusion below the origin of the renal arteries could be carried out without damage for almost any necessary time. Temporary occlusion of the thoracic aorta for resection of aneurysm presented two major difficulties: one was the effect of increased vascular resistance upon the heart, the other was the effect of temporary ischemia upon vital organs. The damaging effect of cross-clamping the thoracic aorta has been minimized by the use of various added techniques. General body hypothermia may prevent ischemic changes in the kidney and spinal cord. Shunting blood around the lesion by way of an exteriorized temporary tube passed through a pump has prevented undue cardiac strain Progress in this field has been rapid and rewarding Aneurysms at all levels of the thoracic and abdominal aorta have been successfully resected with varying degrees of danger. Aside from the technical aspects of the actual resection and replacement, important developments have occurred in the graft material used Originally, *homologous arterial tissue* offered a convenient and satisfactory material for grafts. More recently, however, homologous tissue grafts have been almost completely displaced by *prostheses made of various plastic fabrics.*

In the present discussion, the subject of aortic aneurysm has been divided into three sections, namely, abdominal, descending thoracic, and aortic arch aneurysms, each presents its own particular problems.

ANEURYSMS OF THE ABDOMINAL AORTA

The grave prognosis of abdominal aortic aneurysm and the relative ease with which the diagnosis may be made, makes the early recognition and surgical treatment of this lesion extremely important and entirely feasible. The danger of an abdominal aortic aneurysm is well recognized. Estes reported that, of a series of 102 patients with abdominal aneurysm, only 67 per cent survived 1 year after the diagnosis had been made and only 10 per cent were alive at the end of 8 years. These aneurysms were not productive of symptoms at the time of discovery. Once an aneurysm becomes truly symptomatic, the danger of rupture is tremendously increased.

Abdominal aortic aneurysms are almost exclusively *arteriosclerotic* in origin. *Trauma,* which accounts for a number of aneurysms in the thoracic aorta, has not been truly recorded as the causative factor below the diaphragm *Luetic aneurysms* of the abdominal aorta are undoubtedly extremely rare They have not been encountered in the authors' series. Anatomically, arteriosclerotic aneurysms in this region are essentially fusiform in shape and, in the overwhelming majority, the upper end of the aneurysm lies below the renal arteries

The symptomatology of abdominal aortic aneurysm is based on the effect of the expanding lesion on other structures. Small aneurysms rarely produce any symptoms beyond the complaint of pulsation within the abdomen; this may be experienced by thin patients. Compression of the duodenum at the ligament of Treitz and compression and erosion of the paravertebral ligaments and the vertebral bodies produce the major symptoms Occasionally, an aneurysm in this location may produce sufficient compression of one of the ureters to cause hydronephrosis and renal symptoms.

Diagnosis of Abdominal Aneurysms. The diagnosis of an arteriosclerotic abdominal aneurysm depends on physical examination and radiographic findings. Careful abdominal palpation will disclose the pulsating mass which is often tender. Obesity can obscure even moderately large aneurysms. The pulsating mass is usually more prominent to the left of the midline than to the right, and the discovery of an expansile pulse on the lateral border of such a mass is much more diagnostic than anterior pulsation. When lateral expansion during systole cannot be demonstrated, suspicion arises that the pulsation is transmitted and that an intraabdominal tumor, e g., of the pancreas or stomach, may be present. Simple fatty thickening of the mesentery or omentum may produce a sufficient degree of transmission of the aortic pulse to the abdominal wall as to stimulate suspicion of an aneurysm

Posteroanterior and lateral *roentgenograms* of the abdomen, which should be routine in the work-up of older patients, are diagnostic

for aneurysm when they show a layer of *calcification* in its wall. *Aortography* is usually disappointing in proving the diagnosis of aneurysm in suspicious cases This is because the laminated mural clot, which forms in the distended portions of the lesion, maintains a lumen which appears on aortography essentially normal in size, although irregular in shape This same irregularity is observed in patients with atherosclerosis of the aorta without aneurysm In instances in which the physical examination is diagnostic of aneurysm, aortography is neither desirable nor useful. The danger of displacing the mural thrombus within the aneurysm is considerable while, at the same time, the aortogram which might be considered useful for determining the site of origin of the aneurysm in relation to renal artery branches may fail in this objective.

The serious complications of abdominal aortic aneurysm are *rupture* and *massive thrombosis* Thrombosis of an abdominal aortic aneurysm is a rare occurrence, representing a distinct difference from the behavior of *popliteal* artery aneurysms, in which thrombosis is quite frequent On the other hand, *rupture* is the most frequent cause of death in patients with an abdominal aneurysm.

This catastrophe is likely to be announced by severe continuous abdominal and flank pain. The pain is usually referred to the back The common site of rupture is the posterior wall of the aneurysm, where it impinges on the lumbar spine and has been thinned out by constant compression against the bony structure Less frequent points of rupture are directly anterior into the root of mesentery of the small bowel, and occasionally into the duodenum or the inferior vena cava

When rupture occurs in the usual location, *posteriorly*, the immediate bleeding is *into the* retroperitoneal space of the flank and the pelvis Free bleeding into the peritoneal cavity is delayed, and during this period of delay the amount of blood loss is significant and productive of a shocklike state, even though it is limited by the confines of the retroperitoneal tissues This anatomical situation is fortunate in that it provides an opportunity for the diagnosis to be made and the patient to be transported to a suitable facility for resectional therapy of the ruptured aneurysm The period of delay, before extension of the rupture into the peritoneal cavity, may be very brief or may extend up to a 21-day period (observed in one such case in the authors' series).

On physical examination, the patient exhibits a picture of *shock* of varying degree. A usual diagnostic finding consists of transmitted pulsation in the flank and costovertebral angle where the extraperitoneal collection of blood acts like a pulsating hematoma.

Surgical Techniques. Present-day therapy of infrarenal aneurysms of the aorta consists of extirpation of the aneurysm and restoration with a graft of one type or another.

During the early years of this type of surgery the standard graft material consisted of aortic bifurcations recovered at autopsy from patients whose fatal illness did not affect the usefulness of tissues for grafting. Initially, these were taken from the cadaver under operating-room conditions maintaining sterility of the graft by early removal and very careful attention to asepsis. Such grafts were used *in the fresh* state or were preserved by rapid freezing in dry ice or liquid nitrogen to a temperature far below 0°C. The temperature was −70°C in the case of carbon dioxide snow. This method of removal of graft material was so laborious as to increase the difficulty of obtaining it Therefore,

wet, sterilization by application of ethylene oxide fumes, and finally the sterilization of the freeze

clinical experience certain significant disadvantages have appeared in the use of homologous artery transplants. These involve a variety of patient reactions, in which the recipient's tissue may actually react in a form of rejection (Szylayi) Another disadvantage is that the grafted artery tissue is affected by the general tendency of the recipient to store lipoid material in his vessels. This may actually be more pronounced in the graft than in the patient's other arteries. Finally, it has been demonstrated that there is a distinct loss of strength in arterial tissue when it is subjected to ethylene-oxide or beta-propiolactone sterilization The latter substance particularly produces loss of immediate tensile strength and the ability to hold sutures.

Following the work of Blakemore in demonstrating that tubular prostheses of a plastic cloth (Vinyon N) were reliable as replacements for the abdominal aorta, there has been in the past 3 years a decreased use of homologous arteries for replacement of the abdominal aortic bifurcation in favor

of bifurcations made of plastics. Nylon, Dacron, Orlon, and Teflon have all been tested and have all been satisfactory in varying degrees. Presently, Dacron in a form developed in the author's laboratory and in that of DeBakey and Cooley, as well as nylon in a form developed by Edwards, are in wide use.

Selection of Patients for Surgery. The presence of an abdominal aneurysm is an indication for surgery. Some estimate as to the risk of the operative procedure can be obtained through consideration of several conditions which may be termed "prognostic factors." These factors are (1) age of the patient over 70; (2) the presence of hypertension with a wide pulse pressure; (3) a recent (less than 6 months previously) coronary occlusion, (4) cerebral manifestations of arteriosclerotic disease; and (5) evidence of occlusive arterial disease in the lower extremities In addition to these important factors, it is probably true that obesity increases the hazard of surgery and that nitrogen retention due to renal disease is also a negative factor Table 15-9 indicates the effect of these prognostic factors on the mortality in the authors' series of 103 cases of elective aneurysm resection.

The presence of a number of these factors, however, should not be considered a contraindication for surgery, particularly in the presence of an aneurysm which is either large or symptomatic. This is because of the probability of rupture and death demonstrated by the previously mentioned series.

Preoperative Management. Elective aneurysmectomy should be preceded by a period in which the patient's hydration and cardiac function are brought to the best possible level A significant number of patients have shown some elevation of blood nitrogen due to prostatic hypertrophy, and in these patients a period of bladder decompression is necessary. Digitalization is indicated only if the patient shows heart failure.

The immediate preoperative preparation includes gastrointestinal decompression by continuous suction for a period of several hours, insertion of a urethral catheter in the bladder, and minimal preoperative medication, to prevent depression of respiratory function and blood pressure prior to surgery. Careful cleansing of the lower gastrointestinal tract is accomplished by enemas, never by catharsis.

Experience has proved that vascular anastomoses between major arteries and either homologous grafts or prostheses can be made safely with a single line of fine suture material Attempts to produce an eversion of the vessel ends, in the case of diseased vessels, are likely to fail and in any event are unnecessary. In most cases it is desirable and possible to remove the entire wall of the arteriosclerotic aneurysm. However, in some patients the aneurysm will be so densely adherent to the vena cava as to render its separation from that vessel dangerous In such cases, after removing as much of the total wall as is possible, the inner layers are debrided.

Results of Abdominal Aortic Resection and Graft Replacement. In a small number of cases, resection was performed up to 7 years

TABLE 15-9 EFFECT OF PROGNOSTIC FACTORS* ON MORTALITY IN ELECTIVE RESECTION OF ABDOMINAL ANEURYSM, 82 CASES

Number of factors involved	*Number of patients treated*		
	Total	*Mortality* †	
		Number	*Per cent*
5	3	1	33
4	9	4	44
3	15	4	26
2	38	1	2.6
1	9		
0	8		

* Factors are (1) age over 70, (2) hypertension, (3) myocardial infarct (under 1 year), (4) precordial pain with ECG changes, and (5) obesity.

† Over-all mortality, 12 2 per cent.

prior to the most recent follow-up examination The quantities of cases increase rapidly for periods of time less than 7 years. In the authors' series of 103 aneurysms, the attrition rate from cardiovascular disease and other conditions has been superficially about that which would be expected of patients in this age group The initial mortality rate is presented in Table 15-9

THORACOABDOMINAL ANEURYSMS

Aneurysms of the upper abdominal and lower thoracic aorta fortunately are uncommon The techniques used in their resection take into consideration the danger of producing serious ischemic damage, particularly to the kidneys, but also possibly to liver, adrenal glands, the gastrointestinal tract, and the spinal cord as a consequence of the temporary arrest of blood flow to these organs during the time required to excise the aneurysm and replace it with a graft

The time required for resection and grafting at this level is, of course, greater than would be required for the resection of the infrarenal aorta. This is because two renal artery anastomoses and a reconnection of the superior mesenteric artery and the celiac axis to the graft are required One of the methods developed to overcome this problem consists of the use of *hypothermia* to reduce oxygen demand of the tissues involved. This method, which is entirely adequate for the time required to make two anastomoses for a purely thoracic aneurysm, has not seemed satisfactory in surgery of thoracoabdominal aneurysms.

A second procedure was described by DeBakey It utilizes *a temporary vascular shunt to* conduct blood around the area of partial occlusion while some of the anastomoses are being made This minimizes the period of circulatory arrest to each vascular bed as its artery is handled The authors have used a third method in two cases. *a homologous graft of the thoracoabdominal segment is anastomosed end-to-side to the thoracic aorta above the aneurysm*. This side arm is used for vascularization of all of the visceral branches. As each vital vessel is anastomosed, the blood supply to that organ is reestablished by moving the occluding clamp on the side arm downward below that branch. In this manner, it is possible to reduce the period of temporary occlusion of each of these vessels to about 10 min. After a blood supply is reestablished to the celiac, superior mesenteric, and the two renal arteries through the side-arm graft, the aorta itself may be cross-clamped above and below the aneurysm The diseased segment of aorta is then excised and replaced by a separate graft to restore blood flow to the lower extremities.

Actually, the safe period for temporary occlusion of the visceral branches in the human being is not known Wide variation has been observed in the maximum length of time of vascular occlusion which is tolerated by the kidneys of various species of laboratory animals. Badenoch and Darmody found that rabbit kidney sustains fatal renal damage after 2 hr of renal-artery occlusion. On the other hand, this period of occlusion is well tolerated by the rat kidney. In the rat, a period of occlusion beyond 3 hr causes a 50 *per cent* mortality The dog kidney will tolerate about 2 hr of arterial occlusion with progressive increase in the percentage of mortality after 2 hr. Renal function is temporarily reduced after nonfatal occlusion It gradually returns to normal over a period of 2 to 3 weeks.

Various authors have reported experiences with temporary renal-artery occlusion. Semb noted no significant alteration in renal function after 1½ hr, during which the entire renal pedicle was clamped off while he performed segmental resection of tuberculous portions of kidneys. Bahnson has reported the survival of a patient following occlusion of both renal arteries for 37 min. It is likely that the age of the patient plays a part in the tolerance of renal-artery occlusion and that the arteriosclerotic kidney is much more sensitive.

The tolerance of the liver parenchyma to ischemia has been studied experimentally. The evidence suggests that severe damage approaching fatal change appears after as little as one-half hour of occlusion. There is some [illegible] DeBakey, in his reports on resection of thoracoabdominal aneurysms, produced total hepatic ischemia (except, of course, for portal venous flow) for periods ranging from 44 to 116 min. He observed no instance of disturbance in hepatic function It appears that successful resection of the thoracoabdominal aneurysm may be accomplished

if the period of temporary blockage to the viscera can be kept within safe limits.

ANEURYSMS OF THE DESCENDING THORACIC AORTA

Aneurysms of the descending thoracic aorta arising below the origin of the left subclavian artery are predominantly due to arteriosclerosis but may arise secondary to trauma or syphilitic aortitis In addition, a certain number of fusiform aneurysms in this location are the result of the stabilization of dissecting hematomas of the descending aorta.

As was mentioned earlier, the first method of treatment to receive attention was an attempt to produce *thrombosis of the lumen* of saccular thoracic aneurysms by the introduction of coils of wire. Also in this region, and to some extent in the abdominal aorta, the *wrapping of aneurysms* with some fibrogenic material with the idea of producing scarring was widely used until definitive treatment became available.

Excisional therapy was first applied in the form of *lateral aneurysmectomy* One of the earlier reports by Bahnson (1953) indicated that this method could produce relief of symptoms by excision of the mass whether the aneurysm was in the descending aorta or in some part of the arch. This surgical procedure was not performed many times Several patients who were treated by lateral aneurysmectomy have suffered recurrence of the aneurysm because the remaining portion of the wall of the vessel was weak One such patient was encountered in the authors' series Both of these recurrent aneurysms were resected and the region of the descending aorta replaced by a graft

Resection and graft replacement constitute the ideal method of therapy in that all portions of the aorta which are the site of severe disease may, within limits, be resected Lam and Aram were the first to report excision with graft replacement of an arteriosclerotic aneurysm of the descending thoracic aorta Their patient came to an unfortunate end because of an infection in the aneurysmal sac, which was left behind, but the case and its reporting represented a significant advance in vascular surgery.

The limitation of the amount of aneurysm which may be resected in the descending thoracic area stems from the possibility of interference with the blood supply to the spinal cord. This was actually illustrated by the patient of Lam and Aram, in whom flaccid paraplegia of the lower extremities was noticed until the time of death. In the authors' series, the resection of the entire descending thoracic aorta for aneurysm resulted in fatal damage to the spinal cord. Resection of the thoracic aorta leaving the lower few pairs of intercostal arteries intact is tolerated by the spinal cord without difficulty. Adams and van Geertraden collected from the literature instances of thoracic aortic occlusion for surgery and explained the wide variations in results on the basis of anatomical variations in the blood supply to the spinal cord. It is evident from their study that it is impossible to determine before surgery whether a given length of resection of the thoracic aorta will produce definite cord symptoms.

The second item of importance in the resection of this portion of the aorta arises from the temporary occlusion of blood supply to the organs below the diaphragm. The third consideration consists of the effect on the heart of total cross-clamping of the aorta in this region. These factors and their control through the use of hypotension and hypothermia were reported by the authors (1955). The use of temporary bypasses, from the upper thoracic aorta to a point below the area of resection, provides another method of avoiding complications A similar bypass, energized by a pump, can be made from the left atrium down to an aortic branch such as the femoral artery. This method has been reported by Gerbode and by Cooley, following previous suggestions.

Using one of these methods, resection of the descending thoracic aorta for aneurysm presents relatively little difficulty when one or two distal pairs of intercostal arteries can be left behind. The resection is followed by graft replacement. All of the early resections were done using homologous arteries for the replacement following the early use by Gross and by Swan et al of homologous artery grafts in this region of the aorta. More recently, homologous arteries have in this region, as in almost all others, been superseded by *plastic fabric prostheses*.

Selection of Patients. Indications for resection of thoracic aortic aneurysm are essentially the same for the ascendin[illegible] the arch,

and the descending aorta, because resectional therapy is feasible at all these points.

The symptomatology is almost entirely explainable on the basis of impingement of the aneurysm on other structures. There may be difficulty in swallowing because of compression of the esophagus; voice changes because of disturbance of a recurrent laryngeal nerve; tracheobronchial compression; and severe pain because of erosion of the bony structures of the thorax, principally the vertebral bodies The prognosis in thoracic aneurysm is routinely grave because of the probability of rupture of the aneurysm at a point of compression on bone or some portion of the tracheobronchial tree It is clear that surgical therapy of a thoracic aortic aneurysm is indicated in all cases in which the lesion is discovered, with the limitations imposed by the technical difficulties presented by individual cases Such technical difficulties are rapidly being overcome, with extension of the indications for surgery.

ANEURYSMS OF THE ASCENDING AORTA AND ARCH

Additional technical steps are necessary to permit resection of aneurysms of the arch and the ascending portion of the thoracic aorta. In this region, it is necessary to arrange for a continued blood supply to the cerebral vessels while at the same time the outflow of the heart to major vascular beds in the thorax and abdomen remains unobstructed in order to prevent an unsupportable degree of increase in peripheral resistance

In surgery on the arch of the aorta, this requirement has most frequently been met by the implantation of a suitable *temporary bypass* from the ascending to the descending aorta with the addition of side arms which provide for continued circulation into the carotid arteries. With such a shunt in place, resection of the aneurysm may be accomplished without disturbance of cardiac action or of cerebral flow.

One further requirement must be met for successful surgery on the ascending aorta. This consists of maintenance of coronary-artery flow during the period of occlusion of the aorta just above the heart, or of the necessity to stop the heart for a limited period, thereby making the requirement of coronary flow completely unnecessary.

In lesions confined entirely to the ascending aorta, this problem can be rather simply solved by placing the patient on *total extracorporeal circulation* through pumps and an exterior oxygenator. In the particular use of this equipment, the blood is removed from the circulation from the superior and inferior venae cavae and replaced through a catheter introduced into the femoral artery. The aorta can then be clamped above the heart and below the innominate artery, maintaining coronary circulation by a separate inflow from the perfusion apparatus Studies pointing out the importance of coronary-pulmonary flow seem to indicate that added coronary perfusion under just these circumstances may be unnecessary. This work, which was done in the authors' laboratory, shows the ability of the heart to maintain its own circulation while the remainder of the body is supplied by the extracorporeal pump oxygenator. With this apparatus, the experimental animal can be maintained for long periods, during which some blood must be drained from the coronary-pulmonary circuit at intervals to compensate for bronchial artery flow.

The clinical picture of arteriosclerosis

JEAN LEQUIME AND OLIVIER POLIS

Over the years, human beings ignore what is happening to their blood vessels. The arteries bear the continuous hammering of the arterial pressure; their walls are brushed by the turbulence of the blood and are in contact with the blood, of which the physicochemical properties may change in particular pathological conditions.

When arteriosclerosis begins, this process may assume different clinical forms: Monckeberg's arteriosclerosis, arteriolosclerosis, and atherosclerosis. The pathological aspects that differentiate these three types are related to different causative factors and cause different clinical pictures.

MÖNCKEBERG'S ARTERIOSCLEROSIS

This disease involves the muscular arteries, e.g., the radial, iliac, and intercostal arteries. Subsequent to degenerative phenomena in the media and deposition of calcium salts, the damaged vessel assumes the aspect of a rigid pipe. Even though this type of arteriosclerosis may be regarded as a normal senile process, arterial hypertension favors its development. The caliber of the artery remains unchanged, and consequently there are few symptoms. However, decreased vasomotor activity and reduced blood flow do occur, and, in consequence, increases of systolic pressure and of cardiac work are observed. Subsequently, the sclerosis of the media increases and is often associated with atherosclerosis.

ARTERIOLOSCLEROSIS

This process often involves the preglomerular arterioles of the kidney and the small arteries of the retina. An eosinophilic, amorphous substance accumulates under the endothelium of the arterioles. It has been said that arteriolosclerosis is characteristic of arterial hypertension, but actually it is more a consequence than a cause.

A decrease of the arterial caliber followed by ischemic phenomena is observed. The high peripheral resistance leads to increased diastolic pressure and greater cardiac work.

ATHEROSCLEROSIS

This form is particularly localized in the aorta and the coronary arteries. The lesions are characterized by atheromatous plaques formed by the deposition and accumulation of lipids in the intima plus secondary fibroblastic proliferation. Narrowing of the arterial lumen, caused by the plaques, and thrombosis following their ulceration, explain the symptoms. Sometimes, rupture of the wall occurs and a dissecting aneurysm develops. In general, the destruction of the elastic and muscular layers of the arteries favors dilatation and rupture of the wall, especially if the blood pressure is high.

The *symptoms of arteriosclerosis*, in some cases, appear relatively early. *Diabetes* plays an important role in some cases. In others, *arterial hypertension* seems to be a predispos-

ing factor. While *coronary arteriosclerosis* is more frequent in men than in women below 60 years of age, this predominance is absent in diabetics and decreases in hypertensive patients

Whenever there is evidence of coronary heart disease in young people, familial xanthomatosis and periarteritis nodosa should come under consideration. The *family history* is important in presumed cases of arteriosclerosis. Diabetes, hypertension, xanthomatosis, and the importance of age and sex, have already been mentioned

The *past history*, profession, habits, and other factors should also be carefully discussed Prolonged exposure to cold or humidity might explain vasomotor phenomena, trauma may lead to thrombosis, aneurysms, or vasomotor troubles of the Sudeck type, the role of tobacco has been demonstrated in arteritis of the lower extremities, and certain vascular disorders may follow the use of ergotamine. Thyroid extract, used in hypothyroid patients, may be the cause of precordial pain.

Cardiac Disturbances Due to Atherosclerosis. These are revealed, in some cases, by the clinical picture of heart failure: the patient complains of dyspnea during exertion and orthopnea Also, there is often precordial pain with radiation to the left arm, elicited by exertion and relieved by rest or nitroglycerin. Cold, heavy meals, and unusual exertion favor these attacks. In addition, the classical picture of myocardial infarction may occur.

Atherosclerosis of the Aorta. This condition is frequently asymptomatic, but sometimes, favored by arterial hypertension, a *dissecting aneurysm* may develop This is characterized by severe chest pain, radiating to the back, abdomen, and legs and accompanied by vascular collapse, nausea, dyspnea and, less frequently, dysphagia

Aneurysms. *Abdominal aneurysms*, in contrast with those in the thorax, are generally of atherosclerotic origin. However, those occurring in patients younger than 50 may be syphilitic. These aneurysms may attain a large size and cause various disorders through compression of abdominal organs.

Arteriosclerosis of the Lower Extremities. This form of atherosclerosis causes a typical picture during a walk the patient feels *pain in the calves* that obliges him to stop; the pain is then relieved by a short rest. Such a clinical picture is called *intermittent claudication*. Pain in the legs or cramps in *the calves occurring at night or without exertion*, are evidences of severe ischemia; they sometimes oblige the patient to sleep with his legs dangling out of the bed and are frequently accompanied by *paresthesia*. It should be kept in mind that other conditions may cause similar pain and cramps; coarctation of the aorta and a great number of peripheral vascular diseases are the most common of these. Exposure to cold may cause or favor the symptoms of peripheral ischemia, as proved by the fact that intermittent claudication occurs mostly in the winter. Anemia favors the onset of pain. Even persons with normal peripheral arteries may have pain in the legs if exposed to low *temperatures*

Cerebral Atherosclerosis. In addition to the clinical syndromes of cerebrovascular accidents, cerebral atherosclerosis, due to multiple small lesions, may be accompanied by progressive mental changes: decreases in the intelligence, judgment, and memory, particularly for names and recent events, are common Reminiscing, confabulation, irritability, hostility, egotism, amoral reactions, and even paranoid or demented states, are observed

Arteriolosclerosis of the Kidneys. This is the consequence of chronic arterial hypertension which has dominated the clinical picture for a long time. The patient complains of fatigue, loss of weight, headache, and dyspnea Ankle edema and proteinuria are present. During the evolution of the disease, visual disturbances begin and then epistaxis, itching, digestive troubles, muscular tremors, and cramps are observed. Many patients consulting a doctor for phenomena involving a particular system, reveal, after a complete physical examination, that they are suffering from the results of renal arteriolosclerosis.

DIAGNOSIS

A complete cardiac study is necessary. For instance an aortic stenosis or insufficiency may be the cause of coronary ischemia; left ventricular failure may be either the cause or the result of this ischemia. *Electrocardiograms* in this condition may reveal arrhythmias, conduction disturbances, and changes of repolarization. The exertion and *hypoxia tests* may confirm the diagnosis of coronary insufficiency. A *roent-*

genographic study may reveal enlargement of the heart and dilatation and calcification of the aorta.

The level of blood pressure varies. Arterial blood pressure is frequently normal in atheromatosis of the aorta but may be elevated if there is arteriolosclerosis. Moreover, it should be kept in mind that an increased rigidity of the aorta is followed by some increase of systolic pressure and a decrease of diastolic pressure because the elastic damping of the aortic walls is decreased or absent.

Patients with a *dissecting aneurysm of the aorta* (Chaps. 5 and 6) may present difficult diagnostic problems because the symptoms may simulate those of myocardial infarction, although, on the other hand, a myocardial infarction may occur after the dissection, because of compression of the coronary arteries by the extravasated blood In the differential diagnosis, the persistence of hypertension concurrent with symptoms of shock, sensory and motor difficulties, dysphagia, inequality of the pulses, and sudden onset of aortic insufficiency, are evidence of a dissection The electrocardiogram usually is *not* typical of an infarct

Thoracic aneurysms of atheromatous origin are rare They may be asymptomatic and therefore discovered only through a casual radiographic examination In the case of an *aneurysm of the abdominal aorta,* the x-ray study may show calcification of the wall and vertebral erosion (see Chap 7)

A careful and detailed *examination of the peripheral circulation* is particularly important in arteriosclerotic patients (see Chap 11; also Part 3, Chap 11, The Peripheral Circulation). It should be performed at basal conditions (constant temperature, etc.). Chronic arterial insufficiency may be followed by muscular atrophy of the extremities, chronic infections of the nails, and gangrene Conversely, edema and ulcerations are more frequently due to chronic venous insufficiency than to arterial diseases. Cyanosis is an expression of a slower cutaneous circulation. If the capillary pressure is normal, blanching of the skin, produced by local pressure, should rapidly disappear.

A severe *arterial occlusion* is accompanied by early and diffuse anesthesia, its persistence is of prognostic value. In this condition, elevation of an extremity provokes extreme pallor and lowering it reveals colored spots and slow changes in color. Generally, in an ischemic limb the superficial veins are collapsed and the peripheral venous filling is delayed. A decrease in cutaneous temperature is of particular significance. Palpation, complemented by oscillometry, allows the observer to evaluate the pulsations of the arteries (femoral, popliteal, posterior tibial, and dorsalis pedis). Bilateral absence of the femoral pulses is suggestive of coarctation of the aorta; unilateral absence is generally due to occlusion of the common or external iliac.

Inequality of the femoral pulses may also be due to the presence of an aneurysm

Neurologic signs are frequently found in cerebral arteriosclerosis. It has been stated that the altered vessels may rupture, especially in the presence of arterial hypertension, thus causing a cerebromeningeal hemorrhage However, this concept is being revised and it is now considered that the accumulation of blood is at times caused by thrombosis in an area with rich collateral circulation (*hemorrhagic infarct* of the brain).

The atherosclerotic process narrows the lumen of a vessel causing ischemia and degeneration of the brain tissue. Ulceration of an atheromatous plaque leads to thrombosis of the vessel, but a similar effect may be caused by a sudden drop of blood pressure due to myocardial infarction or other cause. Small arterial lesions, if they are extensive, may also cause various neurologic disturbances Frequent, mild "strokes" followed by moderate neurologic symptoms are observed in such cases. The prognosis is poor and these cases evolve to cachexia and dementia.

Arteriolosclerosis of the kidneys greatly modifies the general condition of the patient The arterial pressure increases, and the diastolic pressure becomes elevated due to the increase in peripheral resistance. As a result, there is hypertrophy of the left ventricle, followed by dilatation of the heart and eventual heart failure.

Examination of the eye grounds reveals exudates, hemorrhages, and papilledema. Anemia is frequent The renal function deteriorates progressively, and this has an important prognostic value proteinuria, hematuria, and nitrogen retention are symptomatic expressions of glomerular damage; tubular injury is shown by renal casts, decreased concentration, and

decreased phenolsulfonphthalein clearance Edema of cardiac or renal origin is frequently present.

Death may be caused by *heart failure* or it may follow a *cerebrovascular attack*. Otherwise, the picture may be that of *uremia:* severe dehydration, anorexia, weakness, disturbances of the electrolyte balance, acidosis with dyspnea and vomiting, hypocalcemia with tetany, secondary hyperparathyroidism with fibrocystic osteitis, convulsions, and hyperpotassemia The latter, which is accompanied by progressive electrocardiographic changes, may cause *ventricular fibrillation* or *standstill* The specific gravity of the patient's urine is usually between 1 008 and 1.012. Ulcerative colitis, diarrhea, and hemorrhages are common

SUMMARY

Some of the clinical aspects of arteriosclerosis have been described. The manifestations usually involve a limited area or a single organ However, it is necessary to remember that these manifestations are related to a diffuse process and that the history and physical examination should be always as complete as possible in order to ascertain the extent of the arterial involvement

genographic study may reveal enlargement of the heart and dilatation and calcification of the aorta.

The level of blood pressure varies. Arterial blood pressure is frequently normal in atheromatosis of the aorta but may be elevated if there is arteriolosclerosis. Moreover, it should be kept in mind that an increased rigidity of the aorta is followed by some increase of systolic pressure and a decrease of diastolic pressure because the elastic damping of the aortic walls is decreased or absent.

Patients with a *dissecting aneurysm of the aorta* (Chaps. 5 and 6) may present difficult diagnostic problems because the symptoms may simulate those of myocardial infarction, although, on the other hand, a myocardial infarction may occur after the dissection, because of compression of the coronary arteries by the extravasated blood In the differential diagnosis, the persistence of hypertension concurrent with symptoms of shock, sensory and motor difficulties, dysphagia, inequality of the pulses, and sudden onset of aortic insufficiency, are evidence of a dissection. The electrocardiogram usually is *not* typical of an infarct.

Thoracic aneurysms of atheromatous origin are rare They may be asymptomatic and therefore discovered only through a casual radiographic examination In the case of an *aneurysm of the abdominal aorta*, the x-ray study may show calcification of the wall and vertebral erosion (see Chap 7)

A careful and detailed *examination of the peripheral circulation* is particularly important in arteriosclerotic patients (see Chap 11, also Part 3, Chap 11, The Peripheral Circulation) It should be performed at basal conditions (constant temperature, etc). Chronic arterial insufficiency may be followed by muscular atrophy of the extremities, chronic infections of the nails, and gangrene. Converselv, edema and ulcerations are more frequently due to chronic venous insufficiency than to arterial diseases. Cyanosis is an expression of a slower cutaneous circulation If the capillary pressure is normal, blanching of the skin, produced by local pressure, should rapidly disappear

A severe *arterial occlusion* is accompanied by early and diffuse anesthesia, its persistence is of prognostic value In this condition, elevation of an extremity provokes extreme pallor and lowering it reveals colored spots and slow changes in color. Generally, in an ischemic limb the superficial veins are collapsed and the peripheral venous filling is delayed. A decrease in cutaneous temperature is of particular significance Palpation, complemented by oscillometry, allows the observer to evaluate the pulsations of the arteries (femoral, popliteal, posterior tibial, and dorsalis pedis). Bilateral absence of the femoral pulses is suggestive of coarctation of the aorta; unilateral absence is generally due to occlusion of the common or external iliac.

Inequality of the femoral pulses may also be due to the presence of an aneurysm

Neurologic signs are frequently found in cerebral arteriosclerosis. It has been stated that the altered vessels may rupture, especially in the presence of arterial hypertension, thus causing a cerebromeningeal hemorrhage. However, this concept is being revised and it is now considered that the accumulation of blood is at times caused by thrombosis in an area with rich collateral circulation (*hemorrhagic infarct* of the brain).

The atherosclerotic process narrows the lumen of a vessel causing ischemia and degeneration of the brain tissue. Ulceration of an atheromatous plaque leads to thrombosis of the vessel, but a similar effect may be caused by a sudden drop of blood pressure due to myocardial infarction or other cause Small arterial lesions, if they are extensive, may also cause various neurologic disturbances. Frequent, mild "strokes" followed by moderate neurologic symptoms are observed in such cases The prognosis is poor and these cases evolve to cachexia and dementia.

Arteriolosclerosis of the kidneys greatly modifies the general condition of the patient. The arterial pressure increases, and the diastolic pressure becomes elevated due to the increase in peripheral resistance. As a result, there is hypertrophy of the left ventricle, followed by dilatation of the heart and eventual heart failure

Examination of the eye grounds reveals exudates, hemorrhages, and papilledema. Anemia is frequent The renal function deteriorates progressively, and this has an important prognostic value proteinuria, hematuria, and nitrogen retention are symptomatic expressions of glomerular damage; tubular injury is shown by renal casts, decreased concentration, and

phenomenon The latter term is applied in instances in which the clinical manifestations of this disorder are superimposed upon organic vascular disease or may occur subsequent to trauma, Sudeck's atrophy (of bone), or intoxication with ergot or heavy metals.

ACROCYANOSIS The benign nature of this disorder has restricted opportunities for its pathologic investigation Intimal thickening of arterioles and dilatation of capillaries and venules have been noted in the skin of affected parts in some instances (Boas, Lewis and Landis)

LIVEDO RETICULARIS Nonspecific changes consisting of intimal hyperplasia of arterioles, similar to that noted in acrocyanosis, have been described (Barker et al) and may be considered as evidence for the vasospastic nature of this disorder.

ERYTHROMELALGIA (ERYTHRALGIA). There have been no records of pathologic studies which might suggest an organic basis for the clinical findings observed in this disease.

EXPOSURE TO COLD The nature of vascular lesions attributed to environmental cold is variable and dependent upon the severity of exposure In patients with the *pernio syndrome*, changes similar to those observed in Raynaud's disease, livedo reticularis, and acrocyanosis have been described After severe exposure to cold, as noted in *trench* or *immersion foot*, vascular engorgement and thrombosis have been noted early With the onset of gangrene, angiitis simulating thromboangiitis obliterans (Friedman), panniculitis, and hemosiderin deposition in perivascular tissues may be evident Medial fibrosis and intimal thickening of small arteries and veins may also be present (Blackwood; White and Warren) It appears significant that similar changes may be encountered in gangrenous areas regardless of cause, particularly in the presence of secondary infection Block found no changes in the skin obtained by biopsy from trench-foot patients who presented no ischemic manifestations In the author's laboratory, studies of several tissue samples from patients with trench foot and gangrene disclosed only moderate intimal thickening of the small arteries in areas unaffected with gangrene

Arteriosclerosis Obliterans. This term is used to designate arteriosclerosis, occurring in the extremities, which causes occlusion of the lumen either by means of the arteriosclerotic process per se or by thrombosis It constitutes the most common type of occlusive vascular disease of the lower extremities Frequently, both the intimal, or atherosclerotic, type of arteriosclerosis, as well as that characterized by alterations within the media, the so-called *medial, senile,* or *Mönckeberg type of sclerosis* are encountered in affected vessels It should be emphasized that vascular occlusion occurs only rarely in cases of Monckeberg's sclerosis in which atherosclerotic changes are not evident (Silbert et al). Medial, or Monckeberg's, sclerosis has been attributed to vascular degeneration associated with aging or "wear and tear." The causes of atherosclerosis have not been completely elucidated. Nutritional, endocrine, biochemical, and local vascular phenomena, including thrombosis (Duguid) and alterations of intimal ground substance (Rinehart and Greenberg), have been implicated in its pathogenesis

Arteriosclerosis obliterans is most frequently encountered in the distal third of the femoral, iliac, and popliteal arteries, although involvement of the tibial arteries is not uncommon Grossly, affected vessels appear thickened, cordlike and, in some areas, unduly brittle. In those instances in which medial calcification is pronounced, the vessels appear beaded due to the segmental distribution of the lesions The lumen, unlike that in normal arteries, appears to be rigidly held open in cross sections of nonoccluded segments Intimal thickening which may appear yellow or gray, depending upon the amount of lipid present, may also be appreciated. In more severely affected segments, intimal *plaques* may seem to completely obliterate the arterial lumen, a similar effect may be produced by thrombosis. Veins and nerves may appear grossly unaffected, although variable thickening of the former is not infrequent Gangrene, if not complicated by secondary infection, imparts a black mummified appearance to the skin. When gangrene has been complicated by infection, the affected part appears moist and is malodorous, there is considerable sloughing of tissue.

Pathology of peripheral vascular diseases

EDWIN R. FISHER

Peripheral vascular diseases include the disorders of blood and lymphatic vessels in the extremities and surface regions of the body. Their pathologic aspects are concerned with alterations in the vessels and secondary disturbances in the tissues. The latter are not specific but appear to be dependent upon the degree of vascular occlusion and ischemia produced The similarities of the pathologic findings and the probable pathogenesis of some of these disorders conveniently allow for their consideration as a group Such a presentation is not intended to represent a rigid classification of these diseases, for undoubtedly revisions will become necessary with accumulation of more information

DISEASES OF ARTERIES

Primarily Functional Disorders. Included in this group of peripheral vascular diseases are those disorders in which physiologic and therapeutic considerations indicate the presence of a primary dysfunction of vasomotor activity rather than organic vascular disease However, relatively nonspecific structural changes may occur in severe or protracted instances. Little is known about the gross appearance of affected vessels, and histological studies have been, for the most part, restricted to those instances in which such sequelae as gangrene have become manifest. It has, therefore, become difficult to delineate vascular alterations which might be secondary to disturbances in the tissues from those of the vascular disease *per se*. Significant pathologic lesions have not been observed during the few studies concerned with possible primary alterations of the nervous system. It is to be noted that many of the disorders to be described may appear clinically during the course of other vascular diseases which are organic in nature In such instances, however, pathologic examination usually will allow for identification of the latter.

RAYNAUD'S DISEASE. It is generally agreed that the clinical findings in this disorder are the result of arterial vasospasm rather than organic vascular disease Arteriographic studies performed on patients with Raynaud's disease have failed to disclose evidence of organic vascular occlusion (Allen). Similarly, pathologic studies, although few, have not revealed lesions in the vessels of affected parts in which there were no trophic or ischemic changes. Lewis (1938) clarified the finding of intimal thickening in cases which were unaccompanied by trophic or ischemic changes by noting similar arterial alterations appeared with increasing age in persons without clinical evidence of Raynaud's disease. However, in those instances in which such secondary phenomena have ensued there may be more severe intimal hyperplasia and thrombosis of digital arteries Experimental evidence strongly suggests that such alterations may result from vasospasm or luminal narrowing (Waters and de Suto-Nagy; Williams, 1952). Raynaud's disease is to be differentiated from Raynaud's

TABLE 15-10 DISTINGUISHING MORPHOLOGIC FEATURES OF ARTERIOSCLEROSIS OBLITERANS AND THROMBOANGIITIS OBLITERANS

Portion of vessel involved	*Arteriosclerosis obliterans*	*Thromboangiitis obliterans*
Lumen	Eccentric	Central
Intima	Atheroma and/or hyalinization	Absence of atheroma; proliferation of endothelial cells
Internal elastic lamina	Disrupted	Preserved, contracted
Media	Usually thinned; fibrosis, calcification, ossification	Slight fibroblastic proliferation and inflammatory cells; preservation of muscle
Adventitia	Slight, irregular fibrosis	Marked fibrosis occasionally encircling vein and nerve
Thrombus	Various stages of organization	Cellular, poorly organized

adherent, reddish purple clot may be observed within the lumen of affected arteries and (rarely) veins In later stages the clot becomes yellowish gray. The adventitia is thickened by dense connective tissue which not infrequently *encircles* adjacent veins and nerve segments, making separation of these structures difficult

Prethrombotic lesions of thromboangiitis have not been adequately characterized, from a morphological point of view However, endothelial proliferation may be observed in portions of arteries in which occlusion has not occurred. In those vessels in which the lesion is well developed, the lumen, which remains centrally placed, is occluded by *a thrombus* containing endothelial cells and relatively numerous fibrocytes, as well as some fibrin, erythrocytes, and a few leucocytes (Fig 15-15B). Organization of such thrombi is usually poorly developed. Multinucleated *giant cells* may be observed at the periphery This location of the giant cells represents one morphologic difference between thromboangiitis obliterans and the so-called "giant-cell arteritis" (temporal arteritis). The internal elastic lamina in thromboangiitis obliterans *is unaffected* and may appear contracted and even thickened The musculature of the *media is* well preserved, although varying degrees of fibroblastic, lymphocytic, and neutrophilic infiltration may be noted in this zone. The adventitia is thickened by proliferation of *connective* tissue which, in long-standing cases, encompasses nerve fibers and adjacent veins The [illegible]
canalized
intact, un[illegible]

sence of deformity of the lumen has been considered as representing specific morphologic features of thromboangiitis obliterans (Hall) The distinguishing morphologic features of thromboangiitis obliterans and arteriosclerosis obliterans are presented in Table 15-10.

Ischemic changes, such as gangrene, osteoporosis, panniculitis, muscular atrophy, and demyelinization of peripheral nerves, may also be observed (Fig. 15-16A).

Necrotizing Angiitis, Including So-called Collagen Diseases. The term "necrotizing angiitis" refers to those vascular diseases in which fibrinoid necrosis in most, but *not all* instances, constitutes a salient morphologic feature of their lesions (See also Part 16, Chap. 3) These disorders include polyarteritis *nodosa*, hypersensitivity angiitis, lupus erythematosus, dermatomyositis, scleroderma, rheumatic arteritis, and rheumatoid arteritis All are frequently [illegible]
various [illegible]
vascular [illegible] cardiac involvement and joint manifestations are not uncommon Because of *these* similarities and apparent locus of reaction in the connective tissues of the body, *these* diseases have been designated as "collagen" diseases However, it has not as yet been convincingly demonstrated that the fibrinoid degeneration characteristic of these disorders *is* derived from the amorphous ground substance *rather* than from fibrillary components of the connective tissue including smooth muscle or from the circulating blood. The results of various histochemical (*Fisher* and Baird; *Muirhead* et al) and immuno-

prised of relatively acellular hyaline connective tissue in which small vascular channels are evident. Cholesterol clefts and, occasionally, lipid-laden macrophages, fibrin, hemosiderin deposits, fresh hemorrhages and calcification may also be observed in this zone. The internal elastic lamina is most often destroyed, at least in part. The media appears thinned and is frequently the site of hyalinization, calcification, and even ossification. The adventitia of affected vessels is usually only moderately thickened (Fig. 15-15A). Osteoporosis, atrophy of skeletal muscles, and degeneration of nerve segments may be evident. There do not appear to be any distinctive morphological features to distinguish the arteriosclerosis obliterans which complicates *diabetes mellitus* from that encountered in nondiabetic patients.

Thromboangiitis Obliterans (Buerger's Disease). The nosologic position of this vascular disease has not been conclusively demonstrated Buerger, on the basis of limited experiments, believed it to be caused by an infectious agent. There has been little subsequent evidence to support this contention. The recognition of visceral involvement in rare instances has prompted some investigators to consider thromboangiitis obliterans to be a form of necrotizing angiitis, similar to polyarteritis nodosa and the other disorders classified as "collagen" diseases. However, the predominantly local nature of this disease, as well as the lack of vascular necrosis, represent features perhaps warranting its distinction from the latter. Vasotoxic agents, such as nicotine, have been implicated as causative factors in thromboangiitis obliterans, although it is now generally agreed that this agent represents only an aggravating or accelerating factor. A few reported instances of this disease in siblings have suggested that heredity may play a role in its pathogenesis (Samuels).

Thromboangiitis obliterans is a disease of medium-sized and small arteries and, not infrequently, veins. Its gross and microscopic appearance may vary in the same vessel, depending upon the age of the individual lesions In the early stages of the disease, affected vessels are segmentally contracted, particularly at sites of occlusion. The veins may be similarly involved and, in rare instances, the latter may be the earliest site of involvement. A soft but

Fig. 15-15. A Cross section of femoral artery from patient with *arteriosclerosis obliterans*. The lumen (1) is eccentric and the site of recent thrombosis An older, organized and recanalized thrombus is also present (2). An atheromatous plaque is evident within the intima (3). B Cross section of tibial artery and vein from patient with *Buerger's disease*. The lumen is centrally placed and occluded by a cellular, poorly organized thrombus (1). The internal elastic lamina (2) is intact. The media (3) is slightly hyalinized The adventitia (4) is only moderately thickened in this instance. A thrombus (5) occludes the lumen of the vein.

TABLE 15-10 DISTINGUISHING MORPHOLOGIC FEATURES OF ARTERIOSCLEROSIS OBLITERANS AND THROMBOANGIITIS OBLITERANS

Portion of vessel involved	*Arteriosclerosis obliterans*	*Thromboangiitis obliterans*
Lumen	Eccentric	Central
Intima	Atheroma and/or hyalinization	Absence of atheroma; proliferation of endothelial cells
Internal elastic lamina	Disrupted	Preserved, contracted
Media	Usually thinned, fibrosis, calcification, ossification	Slight fibroblastic proliferation and inflammatory cells; preservation of muscle
Adventitia	Slight, irregular fibrosis	Marked fibrosis occasionally encircling vein and nerve
Thrombus	Various stages of organization	Cellular, poorly organized

adherent, reddish purple clot may be observed within the lumen of affected arteries and (rarely) veins In later stages the clot becomes yellowish gray The adventitia is thickened by dense connective tissue which not infrequently encircles adjacent veins and nerve segments, making separation of these structures difficult.

Prethrombotic lesions of thromboangiitis have not been adequately characterized, from a morphological point of view However, endothelial proliferation *may* be observed in portions of arteries in which occlusion has *not* occurred In those vessels in which the lesion is well developed, the lumen, which remains centrally placed, is occluded by a *thrombus* containing endothelial cells and relatively numerous fibrocytes, as well as some fibrin, erythrocytes, and a few leucocytes (Fig 15-15B). Organization of such thrombi is usually poorly developed. Multinucleated *giant cells* may be observed at the periphery. This location of the giant cells represents one morphologic difference between thromboangiitis obliterans and the so-called "giant-cell arteritis" (temporal arteritis). The internal elastic lamina in thromboangiitis obliterans is unaffected and may appear contracted and even thickened. The musculature of the media is well preserved, although varying degrees of fibroblastic, lymphocytic, and neutrophilic infiltration may be noted in this zone. The adventitia is thickened by proliferation of connective tissue which, in long-standing cases, encompasses nerve fibers and adjacent veins The appearance of a poorly canalized cellular thrombus surrounded by an intact, undulated elastic membrane in the absence of deformity of the lumen has been considered as representing specific morphologic features of thromboangiitis obliterans (Hall) The distinguishing morphologic features of thromboangiitis obliterans and arteriosclerosis obliterans are presented in Table 15-10.

Ischemic changes, such as gangrene, osteoporosis, panniculitis, muscular atrophy, and demyelinization of peripheral nerves, may also be observed (Fig. 15-16A).

Necrotizing Angiitis, Including So-called Collagen Diseases. The term "necrotizing angiitis" refers to those vascular diseases in which fibrinoid necrosis in *most*, but *not all* instances, constitutes a salient morphologic feature of their lesions (See also Part 16, Chap. 3) These disorders include polyarteritis nodosa, hypersensitivity angiitis, lupus erythematosus, dermatomyositis, scleroderma, rheumatic arteritis, and rheumatoid arteritis. All are frequently associated with vascular alterations in various viscera, as well as with lesions of extravascular connective tissue Cardiac involvement and joint manifestations are not uncommon Because of these similarities and apparent locus of reaction in the connective tissues of the body, these diseases have been designated as "collagen" diseases However, it has not as yet been convincingly demonstrated that the fibrinoid degeneration characteristic of these disorders is derived from the amorphous ground substance rather than from fibrillary components of the connective tissue including smooth muscle or from the circulating blood The results of various histochemical (Fisher and Baird, Muirhead et al) and immuno-

prised of relatively acellular hyaline connective tissue in which small vascular channels are evident. Cholesterol clefts and, occasionally, lipid-laden macrophages, fibrin, hemosiderin deposits, fresh hemorrhages and calcification may also be observed in this zone. The internal elastic lamina is most often destroyed, at least in part. The media appears thinned and is frequently the site of hyalinization, calcification, and even ossification. The adventitia of affected vessels is usually only moderately thickened (Fig. 15-15A). Osteoporosis, atrophy of skeletal muscles, and degeneration of nerve segments may be evident. There do not appear to be any distinctive morphological features to distinguish the arteriosclerosis obliterans which complicates *diabetes mellitus* from that encountered in nondiabetic patients.

Thromboangiitis Obliterans (Buerger's Disease) The nosologic position of this vascular disease has not been conclusively demonstrated. Buerger, on the basis of limited experiments, believed it to be caused by an infectious agent. There has been little subsequent evidence to support this contention The recognition of visceral involvement in rare instances has prompted some investigators to consider thromboangiitis obliterans to be a form of necrotizing angiitis, similar to polyarteritis nodosa and the other disorders classified as "collagen" diseases. However, the predominantly local nature of this disease, as well as the lack of vascular necrosis, represent features perhaps warranting its distinction from the latter. Vasotoxic agents, such as nicotine, have been implicated as causative factors in thromboangiitis obliterans, although it is now generally agreed that this agent represents only an aggravating or accelerating factor. A few reported instances of this disease in siblings have suggested that heredity may play a role in its pathogenesis (Samuels).

Thromboangiitis obliterans is a disease of medium-sized and small arteries and, not infrequently, veins. Its gross and microscopic appearance may vary in the same vessel, depending upon the age of the individual lesions In the early stages of the disease, affected vessels are segmentally contracted, particularly at sites of occlusion. The veins may be similarly involved and, in rare instances, the latter may be the earliest site of involvement. A soft but

B Cross section of tibial artery and vein from patient with *Buerger's disease* The lumen is centrally placed and occluded by a cellular, poorly organized thrombus (1) The internal elastic lamina (2) is intact. The media (3) is slightly hyalinized The adventitia (4) is only moderately thickened in this instance. A thrombus (5) occludes the lumen of the vein.

adventitia and outer media. The *healed stage* reveals marked adventitial sclerosis The media also is the site of scar formation imparting a ragged appearance to the remaining muscle (Fig 15-17A). The intima is markedly thickened by loose, relatively acellular connective tissue containing moderate amounts of chromotropic substance and small capillaries The lumen is markedly narrowed and may be either central or distorted, depending upon the degree of aneurysmal dilatation Thrombi may be canalized. Phenomena less commonly encountered in polyarteritis nodosa are necrotizing granulomas within the wall and adventitial tissues of the affected vessels (Pagel, E R Fisher). Such nodules may appear in apparently healed vessels and represent exacerbation of the disease. Arterioles and veins are not primarily involved in classical examples of polyarteritis nodosa

HYPERSENSITIVITY ANGIITIS This form of necrotizing angiitis (Zeek et al), unlike polyarteritis nodosa, primarily affects arterioles, capillaries, and venules, and the lesions all appear to be in the same stage of development Microscopically, there is moderate endothelial proliferation accompanied by slight to moderate necrosis of the wall of affected vessels, together with infiltration of neutrophils, lymphocytes, and occasional eosinophils Extravasation of erythrocytes may be evident, thus accounting for *petechiae* The healed stage of these lesions has not been adequately described. It is presumed that healing takes place without significant scar formation

LUPUS ERYTHEMATOSUS There is usually notable variation in the intensity of the vascular damage encountered in this disease, which chiefly affects small arteries and arterioles Fibrinoid degeneration within the media is evident Fibroblastic proliferation is observed in the intima of larger vessels and results in narrowing of the lumen Thrombosis, however, is not observed, and the endothelium usually remains intact. Inflammatory cells are most frequently limited to the adventitia Cellular connective tissue may replace areas of degeneration The arteriolar lesions in the skin do not appear specific More pathognomonic vascular changes may be observed in the central arteries of the spleen, these are characterized by ntitial lamination of collagen Renal lesions

B Portion of temporal artery, from patient with *temporal or giant-cell arteritis*, revealing fibrosis of intima (1) and foreign-body giant cells (2) in media

consisting of focal or wire-loop alterations of glomerular basement membranes and "hematoxylin bodies" are strongly suggestive, but not diagnostic, of this disease Valvular lesions of the heart, described by Libman and Sacks, may be found in approximately one-third of the cases

DERMATOMYOSITIS The vascular lesions encountered in dermatom...

chemical studies (Gitlin et al.) tend to suggest that perhaps all three components may contribute to the formation of the fibrinoid tissue and that the contribution of each may vary quantitatively depending upon the site of the degeneration, as well as its duration. It is not an uncommon opinion that all these diseases represent a manifestation of hypersensitivity. On the other hand, it has been emphasized that the similar morphologic manifestations of these diseases do not necessarily imply a common originating cause (Klemperer). However, recent immunohistochemical studies of the lesions of polyarteritis nodosa (Mellors and Ortega), lupus erythematosus, rheumatic fever, and rheumatoid arthritis (Vazquez and Dixon) have demonstrated the presence of excess gamma globulin, a finding which is compatible with, though not unequivocal evidence for, such a pathogenesis

Although the distinctions between some of these disorders may appear artificial, certain anatomical, as well as clinical, differences and therapeutic considerations appear to warrant their individual consideration Giant-cell arteritis (*temporal arteritis*), although occasionally considered in this general group of vascular diseases, appears more properly in the discussion of granulomatous forms of vascular disease.

POLYARTERITIS NODOSA. This disease classically involves medium-sized and small arteries. Peripheral manifestations may appear in about 20 per cent of the cases. Grossly affected vessels appear segmentally thickened Frequently, but not invariably, multiple nodules or aneurysms may be evident. This disorder seems to preferentially affect sites of bifurcation Thrombosis with luminal occlusion and gangrene may occur in the extremities.

Microscopically, the disease has been divided into four stages (Arkin), all of which may be evident in the same patient The earliest or *degenerative stage* is characterized by intimal edema and a fibrinous exudate in this layer (Fig. 15-16A). Endothelial proliferation may also be present. Fibrinoid degeneration of the media may be patchy or circumferentially distributed Infiltration of all vascular coats by neutrophils may be observed in the second, or inflammatory, stage During this stage, there is focal disruption of the internal, and occasionally external, elastic laminas, and aneurysmal dilatation may occur. Thrombosis is not infrequent The third, or *reparative, stage* is characterized by fibroblastic proliferation in the

Fig. 15-16 A. Cross section of tibial nerve, from patient with *Buerger's disease*, revealing extreme perineural fibrosis. B. Cross section of small artery of leg from patient with *polyarteritis nodosa* The lesion is considered early with intimal deposition of fibrin (1), slight medial (2) and adventitial (3) inflammation. Necrosis of the media is focal and of mild degree

thrombi Degeneration of the vascular media and lamina elastica interna, as well as hemorrhage into the adventitia, has been noted in experimentally produced arterial embolism (Cosset et al)

Granulomatous Arteritis Syphilitic, tuberculous, and so-called giant-cell or temporal arteritis are all considered to be forms of granulomatous arteritis. However, the exact nosologic position of the latter is not clear Some investigators have considered it to be a form of "collagen disease" Involvement of visceral vessels has been described (Chasnoff and Vorzimer)

SYPHILIS AND TUBERCULOSIS Syphilis or tuberculosis of peripheral arteries is extremely rare The former may assume a gummatous or, more frequently, an endarteritic form characterized by pronounced endothelial proliferation (Moritz) The media appears intact, although the adventitia may be the site of fibrous thickening.

GIANT-CELL ARTERITIS (TEMPORAL ARTERITIS) In giant-cell arteritis, affected vessels grossly appear nodular and thickened Microscopically, there is often pronounced intimal sclerosis, and although thrombosis is unusual it may occur (Fig 15-17B) The internal elastic lamina appears fragmented and the media, particularly its inner portion, is infiltrated with lymphocytes, neutrophils, and plasma cells Macrophages are conspicuous in areas of necrosis Multinucleated giant cells of the foreign-body type are characteristically noted on the medial aspect of the internal elastic lamina and portions of the latter may occasionally be identified in their cytoplasms with appropriate staining techniques Infiltration of lymphocytes and plasma cells may be noted in the adventitia.

DISEASES OF VEINS

Varicose Veins. Varicosities occur most frequently in the long saphenous vein and its tributaries or in other superficial veins of the lower extremities Only rarely are the deep veins involved. Grossly, involved veins appear tortuous, dilated, and thickened, although the wall may appear thin at sites of severe involvement The valves may appear flattened with widening of their commissures, and distal eversion of these structures may occur (Edwards and Edwards) Since ectasia in the spontaneous type of varicose veins is first observed distal to the valves, it is believed that valvular involvement represents a secondary event (Allen et al) The soft tissues of the extremity may be edematous, and ulceration of the skin

tinguishable from those of lupus erythematosus. Involvement of skeletal muscle, however, appears to be more frequently associated with the former. The affected muscles reveal areas of lymphocytic and neutrophil infiltration with necrosis of muscle fibers, as well as other evidence of degenerative change in these structures, notably proliferation of sarcolemmic cells.

SCLERODERMA. In contrast to the lesions characteristic of the preceding two disorders, fibrinoid degeneration of vessels in scleroderma is unusual. More frequently, the vessels of the skin reveal collagenic changes of their walls, together with marked luminal narrowing. Intimal proliferation may also be pronounced. Inflammatory infiltrate is most often absent, although it may be present in early lesions in the adventitia of affected vessels. The corium in well-developed cases demonstrates homogenization, as well as an apparent increase in collagen and corresponding loss of dermal lamina elastica interna. Skin appendages may be obliterated. The epidermis reveals atrophy. Underlying subcutaneous adipose tissue may reveal inflammatory infiltrate and necrosis, fibrosis, and calcification. Ulceration of the digits and gangrene may occur. The lesions in generalized scleroderma are similar in appearance to those encountered in morphea and acrosclerosis (O'Leary and Waisman), the latter representing a localized sclerodermatous process confined to the upper extremities, face, and chest.

RHEUMATOID ARTERITIS. An arteritis affecting small muscular arteries has been described in occasional patients with rheumatoid arthritis (Sokoloff et al., Cruikshank). Although most frequently noted in striated muscle, such vascular involvement may be systemic. The morphologic appearance of the vessels is superficially similar to that noted in polyarteritis nodosa. However, the inflammatory changes appear to be milder and are restricted principally to the adventitia. Aneurysmal dilatation has not been noted and thrombosis is infrequent. Necrosis of the media is often slight.

RHEUMATIC ARTERITIS. Occasionally, patients with rheumatic fever exhibit a disseminated arteritis, principally of large and small arteries, and occasionally of capillaries (von Glahn and Pappenheimer). The endothelium of the involved vessels is usually intact, and thrombosis is rare. The vessel is thickened by a fibrinous exudate into the intima and media. Moderate to marked medial necrosis may also be noted. The internal elastic lamina may be partially destroyed. Neutrophils, lymphocytes, and occasional eosinophils may be observed in the wall and adventitia. The latter also exhibits edema of connective tissue. Healing by scar formation occurs. Periadventitial sclerosis of the degree noted in polyarteritis nodosa, however, is usually not encountered.

The characteristic features of the various necrotizing angiitides and collagen diseases which may affect the extremities are tabulated in Table 15-11.

Arterial Thrombosis and Embolism. Thrombosis is a frequent finding in arteries affected with arteriosclerosis obliterans or thromboangiitis obliterans. In the absence of antecedent vascular disease, such an event may occur during the course of various infectious diseases; in blood dyscrasias, particularly polycythemia vera; in severe heart failure; and following either acute or chronic trauma. The appearance of the thrombi is similar to that noted in thrombosis of veins. Microscopically, in the primary form, there is little if any inflammatory response noted in the wall of affected vessels. However, when thrombosis results from trauma reactive changes may be conspicuous, although even these changes may include no apparent alteration of the adventitia or wall of the vessel. In this instance, *thrombosis* apparently results from damage to the endothelium caused by transmission of the traumatizing force to this vascular layer (Anderson).

Emboli in the peripheral vessels are most frequently derived from thrombi formed within the heart during episodes of atrial fibrillation or following myocardial infarction or endocarditis. Less frequent sites of origin for emboli are thrombi in aortic aneurysms or on the surface of arteriosclerotic aortic plaques. Thrombi within pulmonary veins or in peripheral veins rarely give rise to arterial embolism. This only occurs when a patent foramen ovale is present, and such a phenomenon is called *paradoxical embolism*. Morphological distinction of emboli from thrombi is often impossible once organization has begun. However, at early stages emboli may appear with little or none of the marginal organization characteristic of

TABLE 15-11. PATHOLOGIC FEATURES OF NECROTIZING ANGIITIDES, INCLUDING "COLLAGEN" DISEASES

thrombi. Degeneration of the vascular media and lamina elastica interna, as well as hemorrhage into the adventitia, has been noted in experimentally produced arterial embolism (Gosset et al.).

Granulomatous Arteritis. Syphilitic, tuberculous, and so-called giant-cell or temporal arteritis are all considered to be forms of granulomatous arteritis. However, the exact nosologic position of the latter is not clear. Some investigators have considered it to be a form of "collagen disease." Involvement of visceral vessels has been described (Chasnoff and Vorzimer).

SYPHILIS AND TUBERCULOSIS. Syphilis or tuberculosis of peripheral arteries is extremely rare. The former may assume a gummatous or, more frequently, an endarteritic form characterized by pronounced endothelial proliferation (Moritz). The media appears intact, although the adventitia may be the site of fibrous thickening.

GIANT-CELL ARTERITIS (TEMPORAL ARTERITIS). In giant-cell arteritis, affected vessels grossly appear nodular and thickened. Microscopically, there is often pronounced intimal sclerosis, and although thrombosis is unusual it may occur (Fig. 15-17B). The internal elastic lamina appears fragmented and the media, particularly its inner portion, is infiltrated with lymphocytes, neutrophils, and plasma cells. Macrophages are conspicuous in areas of necrosis. Multinucleated giant cells of the foreign-body type are characteristically noted on the medial aspect of the internal elastic lamina and portions of the latter may occasionally be identified in their cytoplasms with appropriate staining techniques. Infiltration of lymphocytes and plasma cells may be noted in the adventitia.

DISEASES OF VEINS

Varicose Veins. Varicosities occur most frequently in the long saphenous vein and its tributaries or in other superficial veins of the lower extremities. Only rarely are the deep veins involved. Grossly, involved veins appear tortuous, dilated, and thickened, although the wall may appear thin at sites of severe involvement. The valves may appear flattened with widening of their commissures, and distal eversion of these structures may occur (Edwards and Edwards). Since ectasia in the spontaneous type of varicose veins is first observed distal to the valves, it is believed that valvular involvement represents a secondary event (Allen et al.). The soft tissues of the extremity may be edematous, and ulceration of the skin

or stasis dermatitis may complicate protracted cases.

Microscopically, there is frequently hypertrophy of medial musculature, although in some segments the wall may appear thinned and fibrotic. The lamina elastica interna may appear normal. In areas where there is medial fibrosis, the fibers may be disrupted or absent. The intima is frequently the site of moderate sclerosis characterized by eccentric deposition of relatively acellular hyaline connective tissue. Thrombosis is occasionally noted.

Thrombophlebitis and Phlebothrombosis. Although it is not uncommon to observe a certain degree of inflammatory change within veins occluded by thrombi, the distinction between thrombophlebitis, in which this change is pronounced, and phlebothrombosis, a more bland lesion, appears warranted (Ochsner and DeBakey) The former may result from infection, or chemically or physically induced trauma, whereas in phlebothrombosis such inciting agents are not evident Stasis, alterations in endothelial cells, and alteration of the chemical and physical properties of the blood, factors considered essential for thrombus formation, may or may not be apparently operative in all instances of phlebothrombosis. The type of venous thrombosis (in the extremities) which may accompany some mucin-secreting carcinomas, particularly those of the pancreas, lung, or gallbladder, resembles other instances of phlebothrombosis (Fisher and Baird). The exact nature of this association has not been clearly elucidated

The gross appearance of affected veins will vary depending upon the degree of inflammation, as well as the duration of the pathologic changes. In thrombophlebitis, the vein appears thickened and edematous, in phlebothrombosis it may appear relatively normal. The *luminal thrombus* at the site of occlusion in thrombophlebitis is characteristically adherent to the lining of the vessel but, in phlebothrombosis (at least early in its course), it may be removed with greater ease. These observations indicate a relationship with the more frequent occurrence of *pulmonary emboli* in the latter In both instances, the color of the thrombus at its initial site of formation depends upon the relative quantities of platelets, fibrin, leucocytes, and erythrocytes. Those thrombi in which the last are abundant appear red as opposed to the gray color of clots comprised principally of platelets and fibrin. The *lines of Zahn*, characteristic of ante-mortem thrombi, may be frequently observed. Propagation of the thrombus in the form of a red "tail" usually occurs proximally in the direction of the circulation. "Tail" formation appears to be more frequent in phlebothrombosis, and the thrombi removed from the veins or pulmonary artery following embolization frequently appear as casts of the vein of origin and its tributaries The vein may appear cordlike after recovery from thrombophlebitis. The lumen in both forms of venous thrombosis may be either partially or completely occluded, depending upon the degree of organization and canalization of the preexisting thrombus.

Microscopically, the *thrombus* is observed to be comprised of varying proportions of laminated masses of fibrin and platelets separating leucocytes and erythrocytes. Organization proceeds from the periphery of the clot; it is characterized by the proliferation of fibroblasts and newly formed capillaries. The end result of this process is a fibrous plaque containing vascular spaces of varying size. The luminal surface of incompletely occluding thrombi may be covered by regenerated endothelial cells The walls of thrombophlebitic veins reveal edema and marked inflammatory infiltration as well as fibroblastic proliferation. On the other hand, only mild inflammatory change is observed in phlebothrombosis, and this is usually confined to the inner medial and intimal coats The adventitia and surrounding tissue are also frequently affected by inflammation in thrombophlebitis.

Phlebosclerosis. Focal intimal sclerosis is not infrequently encountered in the veins of elderly persons. Similar changes have also been noted in the popliteal veins of newborn infants (Lev and Saphir) and is considered by some authors (Hauswirth and Eisenberg) to comprise a distinct entity in young persons The origin and pathogenesis of *phlebosclerosis* have not been defined and it is unlikely that such a lesion is clinically significant Phlebosclerotic changes are unlike the atherosclerotic changes in arteries, since lipid deposits and calcification are not observed Scott recently demonstrated the similarity between this intimal change and that observed following the organization of thrombi and has suggested that

many cases may be the result of this process. Grossly, involved veins are narrow and their lumens variably compensated. Complete occlusion is unusual. Microscopically, the lumen appears to be narrowed by flat or protuberant deposits of relatively acellular connective tissue containing moderate amounts of chromotropic substance On occasion, small capillary spaces and moderate fibroblastic proliferation may be noted Hemosiderin deposits are variable Similar intimal changes are not unusual in varicose veins The wall may appear unaffected or be thin as the result of fibrosis

DISEASES OF LYMPHATICS

The swelling of soft tissues resulting from an excessive accumulation of lymph (*lymphedema*) may be the result of inflammatory or noninflammatory disorders affecting the lymphatic vessels. Noninflammatory lymphedema appearing spontaneously in the lower extremities of young girls between the ages of 9 and 25 has been designated as lymphedema precox It was the most frequent form of lymphedema encountered in 300 cases of this condition by Allen et al Congenital lymphedema, also noninflammatory, may be hereditary, in which instance it is referred to as *Milroy's disease* (Milroy) The swelling of an extremity resulting from the obstruction of lymphatics and nodes by metastatic tumors or postirradiation fibrosis, and that following resection of lymphatic structures (as in the treatment of malignant neoplasms) are also of the noninflammatory type Lymphangitis, filariasis, or local injury is responsible for the vast majority of inflammatory forms of lymphedema.

In congenital [illegible] sues [illegible] a rela[illegible]tion is most conspicuous about the deep fascia A decrease of fatty tissue in the affected part is notable.

The microscopic appearance of congenital edema has been considered characteristic and distinct from other forms (Mason and Allen) Replacement *of much* of the adipose tissue by markedly dilated or telangiectatic lymph spaces containing a simple endothelial lining is outstanding These channels are separated by loosely formed connective tissue The corium of the overlying skin is thickened Evidence of inflammation or alterations of blood vessels is absent. On the other hand, in inflammatory forms of lymphedema, many of the lymphatic vessels may contain thrombi or be occluded as a result of the inflammatory process. Angitis and fibrosis of the supporting tissues may also be apparent.

TUMORS OF PERIPHERAL VESSELS

The multiplicity of terms utilized in the nomenclature of tumors of blood and lymphatic vessels has resulted in much confusion concerning their classification. Furthermore, there is often great difficulty in distinguishing those tumors considered to be true neoplasms from hamartomatous growths, malformations, and simple ectasias. The following classification, although perhaps oversimplified, appears to be of practical value. The gross *appearance of tumors* of peripheral vessels is highly variable and is largely dependent on the number of vascular channels present and their structure: they are red, purple or blue, as well as pale or colorless. They may or may not be compressible, their growth may be circumscribed or diffuse, furthermore, encapsulation is uncommon

Blood Vessels. HEMANGIOMA The typical hemangioma is a benign, circumscribed, unencapsulated neoplasm consisting of blood vessels formed by vascular channels lined with a single layer of normal-appearing endothelial cells, and having a delicate wall *comprised* principally of reticulum fibers Adventitial cells *may* also be somewhat *conspicuous and newly formed* vascular buds may be recognized Those tumors in which *the vascular* spaces are small and slitlike have been *referred* to as *capillary hemangiomas*, whereas those characterized by large channels are described as *cavernous forms* Such *lesions are* frequently congenital. The *sclerosing hemangioma* is characterized by relatively occult vascular *channels with* a simple endothelial lining surrounded by curlicues of dense *collagen* Foam cells, as well as *hemosiderin-laden* macrophages, may be observed *in the* stroma.

HEMANGIOENDOTHELIOMA. This term is reserved for those tumors in which there is a neoplastic proliferation of endothelial cells *Occasionally*, the lumens may exhibit papillary formation. *Such lesions* are usually slow-growing and may metastasize *relatively late in* their development.

HEMANGIOPERICYTOMA. Evidence suggests that this neoplasm arises from the adventitial pericytes of vascular channels (Stout and Murray; Fisher et al.). Not infrequently such spaces are occult with routine staining techniques, but are well demonstrated by reticulum methods which also reveal the extravaginal position of the tumor cells. The latter most frequently are spindle-shaped, with a whorled distribution about the vascular spaces. Groups of tumor cells are separated by varying quantities of stromal connective tissue Metastases have been observed in about one-third of the patients in one series (McCormack and Gallivan), and isolated reports of such behavior have not been infrequent. There seem to be no histologic characteristics which would enable one to predict such an event.

GLOMUS TUMOR. This tumor represents another vascular neoplasm derived from pericytes, most often at sites where normally there are small arteriovenous shunts, the *Sucquet-Hoyer canals* However, they also have been noted in such sites as the stomach where such structures are not evident (Kay et al). Morphologically, typical examples exhibit adenomatoid formations of rounded perithelial cells Nonmedullated nerve fibers may also be identified. A reticulum stain reveals fibers surrounding individual cells, whereas, in hemangiopericytoma, reticular cells are distributed about groups of tumor cells Such lesions are frequently, but not invariably, exquisitely tender They are benign.

ANGIOSARCOMA The term "angiosarcoma" is commonly utilized in reference to all malignant tumors of vascular origin The author has reserved this term for those lesions resembling fibrosarcomas in which the tumor cells tend to form vascular spaces Such neoplasms are rare It is apparent that, in many instances, differentiation from a highly vascularized fibrosarcoma may be impossible. Their behavior appears to be similar to that of other sarcomas

KAPOSI'S SARCOMA. Kaposi's sarcoma is that form of vascular neoplasm characterized by a variable histological picture apparent not only in different sites but in a single lesion In (perhaps) the early phase it appears as a simple hemangioma associated with intervascular collections of hemosiderin-laden macrophages and histiocytes and a few lymphocytes Later, hemangioendotheliomatous areas, as well as fibrosarcomatous or true angiosarcomatous elements, become evident. It is as yet not clear whether the multiple lesions observed in many instances represent true metastases or autochthonous growths. Lymphedema, apparently resulting from lymphatic obstruction, is not uncommon in the extremities

HAMARTOMAS. This term refers to those vascular tumors in which smooth-muscle elements can be identified within the wall of the component vessels. Certain vascular anomalies with a distinct clinical picture have also been considered hamartomatous (Landing and Farber). These include the syndromes of angiomas of the face and ipsilateral cerebral cortex (Sturge-Weber), cerebellar, retinal, and visceral angiomas with adenomas of the kidney and hepatic and pancreatic cysts (Lindau-von Hippel), and angiomas with dyschondroplasia (Maffucci) Morphologically, the latter contain both hemangiomatous and hemangioendothelial components.

MALFORMATIONS. Included in this category are the various arteriovenous fistulis or aneurysms In the extremities, these are frequently traumatic in origin. The venous segment reveals marked intimal thickening

Lymphatic Vessels. LYMPHANGIOMA, LYMPHANGIOENDOTHELIOMA, AND LYMPHANGIOPERICYTOMA These are the lymphatic counterparts of similar neoplasms of blood vessels. Their distinction from the latter is largely based on the absence of erythrocytes within the vascular compartments.

POSTMASTECTOMY LYMPHANGIOSARCOMA Six cases of this unusual vascular lesion were first reported by Stewart and Treves (1948) as a complication of postmastectomy lymphedema Since then, 20 cases have been recorded (Hermann and Gruhn). Metastases are not infrequent. Morphologically, the lesions are similar in appearance to those of Kaposi's sarcoma, particularly the hemangioendotheliomatous components of this form of vascular neoplasm

11

Clinical aspects of peripheral vascular diseases

DAVID I. ABRAMSON

THROMBOANGIITIS OBLITERANS (BUERGER'S DISEASE)

Thromboangiitis obliterans is a generalized vascular disorder with the predominant changes occurring in the extremities It primarily affects young men and is characterized by remissions and exacerbations Whereas at one time it was believed that the disease affected only Jews of Slavic extraction, this view is no longer accepted For example, a recent study of the incidence of thromboangiitis obliterans in a vascular center set up by the Army during World War II revealed that Jews made up only 8 3 per cent of the series (Abramson)

Causes No causative agent has been established, although several have been proposed. Among them are the ingestion of bread made of grain containing ergot as a contaminant, dermatophytosis, and typhus fever Tobacco smoking has also been implicated and, in the view of some workers (Silbert), it is the principal if not the sole cause of the disease.

Clinical Picture and Course. VENOUS INVOLVEMENT In about 40 per cent of cases, the early state of thromboangiitis obliterans is characterized by pathologic alterations in the superficial veins, producing segmental thrombosis. Because of the fleeting character of the process and because of the unpredictable manner in which it travels from segment to segment of the same and different vessels, it has been given the name of *superficial migratory thrombophlebitis*. Veins of several limbs may be affected simultaneously. Despite the widespread response in the extremities, the condition is not associated with any systemic changes Eventually the phlebitic process may disappear and be replaced by signs of arterial impairment, or both may be present at the same time.

ARTERIAL INVOLVEMENT. During the early stage of pathologic changes in the arterial tree, a diagnosis of thromboangiitis obliterans may be difficult to make The complaints generally consist of *vague pains* in the muscles of the calf or foot, produced by walking long distances and disappearing soon after the patient rests (*mild intermittent claudication*). The associated objective findings are also minimal. The pulsations in the main vessels of the extremities are readily palpable, although there may be a slight decrease in amplitude of one or more, as compared with the arteries on the opposite normal side The various tests for arterial insufficiency are usually too gross to be of value in determining the presence of an impaired arterial circulation.

As the occlusive process advances, the clinical picture comes into better focus Clear-cut *intermittent claudication* is now experienced in one or both lower extremities on walking relatively shorter distances, although symptoms are generally not present at rest. *Pulsations are definitely reduced in one or several peripheral*

arteries, and this finding is confirmed by decreased oscillometric readings, at least for the lower portion of the leg. Slightly abnormal color changes and a lowered skin temperature may also be noted

Further progression of the disease is manifested by the appearance of *rest pain* due to an associated ischemic neuritis. At this stage, the claudication distance may have fallen to as low as one-half of the average city block. A more marked reduction or even absence of pulsations may now be present, associated with decreased or absent oscillometric readings at the various levels on the leg and thigh. Invariably a positive plantar pallor test and a delayed venous filling time (Part 3, Chap 11, The Peripheral Circulation) can be elicited in the involved limb.

Finally, as the circulation to the skin becomes insufficient to take care of its metabolic needs even at rest, slight trauma may be enough to initiate trophic disturbances, such as an *ulcer* or *gangrene* (Fig. 15-18); lesions may also arise spontaneously. Secondary infection may occur, although this is not as frequent as in the case of arteriosclerosis obliterans No difficulty should be encountered in making the diagnosis at this stage since signs of a very severe degree of arterial impairment are obvious.

Prognosis. Provided the pathologic process in thromboangiitis obliterans is limited to the blood vessels in the extremities, and the relatively rare involvement of the arteries of the heart and brain has not occurred, the prognosis as to life is good. However, portions of limbs or entire limbs may be lost if the patient does not abide by the proper therapeutic regimen. On the other hand, if he follows medical instructions, he will probably live a normal life span without the appearance of nutritional disturbances, although his physical activity will be limited by the severity of the intermittent claudication.

Treatment. ABSTINENCE FROM SMOKING The most important single therapeutic approach in thromboangiitis obliterans is *abstinence from smoking*. If the patient cooperates in this regard, it is a good possibility that there will be no further progression of the obliterative process and that the symptoms will become less severe as a result of the simultaneous and unimpeded growth of collateral circulation On the other hand, if smoking is continued, even though markedly reduced, almost invariably there will be an exaggeration of complaints and an increased probability of developing ulcerations and gangrene

PHYSICAL ACTIVITY. The question always arises as to how much exercise the patient with thromboangiitis obliterans should be permitted to do In general it can be stated that, if he is free of nutritional disturbances, he should be advised to determine the range of effort that is possible without producing intermittent claudication and to stay within it. However, some workers believe that graded exercises are of value because of the possibility that the load placed on the vascular tree in the affected extremity will act as a stimulus for further

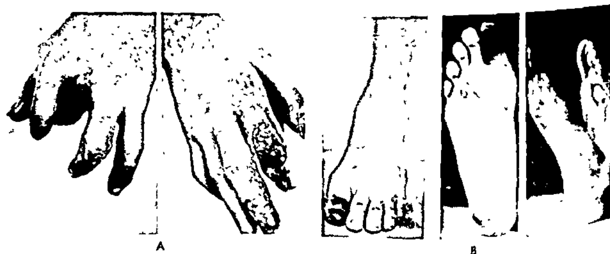

Fig. 15-18. Trophic changes in thromboangiitis obliterans. A. Ulceration and gangrene of fingers, with previous amputation of one digit. B. Gangrene of great toe.

growth of collateral vessels. In any event, at no time should the patient continue to walk after the pain has become severe; otherwise, irreversible changes might occur in the involved muscles. A life of physical inactivity should be discouraged, since it may lead to disuse atrophy of the muscles of the lower extremities, producing further impairment of walking, and also mental deterioration and the adoption of the role of an incurable invalid. It is necessary to point out to the patient that the onset of intermittent claudication involves no serious consequences, the pain acting merely as a deterrent to further physical activity.

In order to increase his walking distance, the patient should attempt certain simple procedures. He will soon learn that, if he reduces his usual pace considerably, he will be able to cover much more ground before having to stop as a result of the pain. Some individuals find the use of a cane efficacious, since by this means the weight placed on the involved extremity is reduced. Others learn that, if they walk stiff-legged without bending their knees or using their calf muscles to any degree, walking distance will also be prolonged.

LOCAL CARE OF THE EXTREMITIES. Of great importance in the prevention of nutritional disturbances is the proper local care of the limbs. This involves a detailed explanation by the physician of the various measures that the patient must take, as well as a discussion of the possible serious consequences of their neglect. A printed or mimeographed list of directions, such as is presented below, may help remind the patient of his role in the therapeutic regimen.

Local hygiene and protection of the limbs are important points to emphasize. The feet should be washed daily with lukewarm water and soap and thoroughly dried, especially between the toes, since moisture at these sites may be responsible for the appearance of a fungus infection. It is advisable to keep the skin of the foot, particularly that of the heel, soft by the use of some type of lotion containing a lanolin base.

Since cold is a very potent vasoconstricting stimulus, it is necessary to reduce exposure of the extremities to this agent as much as possible. In the winter months, the patient should wear woolen socks and full-length woolen drawers. The rest of his body should be kept warm, in order to prevent reflex vasoconstriction in the feet.

Another very important point is the protection of the affected extremity from injury. If his work involves exposure to trauma, it is advisable for the patient to change his job. He should always wear shoes that are well constructed and of the proper size, in order to prevent the formation of blisters. Some type of metal covering on the tip of the shoe may be useful in protecting the toes from possible injury. The toenails should be trimmed carefully and not too closely, and the sides of the nails should not be touched.

The treatment of ingrowing toenails, corns, callouses, and bunions should not be attempted by the patient, but should be carried out by a physician or chiropodist who is acquainted with the fact that a *reduced local* blood flow exists. Even slight abrasions, blisters, or burns should receive special *consideration*, and the ordinary type of antiseptic, e.g., *tincture of iodine* or Mercurochrome, should *not* be used in their treatment. For the same *reason*, any type of corn plaster is contraindicated. Fungus infections should be treated immediately and thoroughly, using mild fungicides, such as a combination of zinc undecylenate, undecylenic acid, and talcum (*Desenex*), 10 per cent undecylenic acid (*Timofax*), propionates and caprylate compound (*Sopronol*), and Asterol dihydrochloride.

TREATMENT OF ISCHEMIC NEURITIS. Therapy in the control of ischemic neuritis is generally *not very effective*. This is especially true for the shooting pains and paresthesias *experienced* when the patient prepares for sleep. Nevertheless it is worthwhile to give *vitamin* B_{12} a clinical trial, using intramuscular injections of 50 or 60 µg two or three times a week. Large doses of thiamine chloride by mouth (200 mg three or four times a day) and the intramuscular injection of crude liver extract may also be of value.

SYMPATHECTOMY. The role of sympathectomy as a therapeutic agent in thromboangiitis obliterans has *not* been established. There is considerable physiological and clinical evidence to support the *view that this* procedure is of little (if any) use in increasing claudication distance, and hence it *should* not be utilized for such a purpose alone. Whether or not

sympathectomy acts to prevent the appearance of nutritional disturbances cannot be determined on the basis of available evidence. Its use in the presence of an ulcer or gangrene is discussed below.

TREATMENT OF ULCERATIVE OR GANGRENOUS LESIONS. *Control of Infection.* In the presence of a nutritional disturbance, it is essential first to control any secondary infection, since otherwise progression of the lesion will occur, due to further embarrassment of the local blood supply. Bed rest is important in order to prevent spread of the inflammatory process. Smears of the secretions should be obtained from the lesion, and cultures grown therefrom, to determine the types of bacteria, and, through sensitivity tests, the proper antibacterial agents to be used These should be applied locally and also administered parenterally

Use of Vasodilating Agents. Attempts should be made to improve the cutaneous circulation through the use of drugs and procedures which either temporarily or permanently remove vasomotor tonus or augment the blood supply of the skin through some other means. Of value in this regard are the various adrenergic blocking agents, such as *Priscoline, Dibenzyline, Hydergine*, and *nicotinic acid* The application of heat to distant portions of the body, to produce reflex or indirect vasodilatation of the blood vessels in the involved extremity, is a worth-while procedure, as is the oral use of whiskey The various mechanical procedures, such as *postural exercises* (Buerger's exercises), *Sanders' oscillating bed, pavaex boot*, and *intermittent venous occlusion*, are of little use in the treatment of an ulcer or gangrene.

Sympathectomy is of value in delineating the lesion, and, if gangrenous digits are to be removed, in facilitating healing of the stumps. However, if extension of the process onto the adjoining portion of the foot or hand has occurred, the operation is not indicated Whether or not it permits a lower level of amputation of an extremity cannot be determined on the basis of available evidence

GENERAL DIRECTIONS FOR CARE OF THE FEET

1. Wash feet each night with a facial soap and warm water.

2. Dry feet with a clean soft rag *without* rubbing the skin. Dry carefully between the toes.

3. Always keep your feet warm Wear woolen socks or wool-lined shoes in the winter and white cotton socks in warm weather. Use a clean pair of socks each day.

4. Wear loosely fitting bed socks.

5. Never apply a hot-water bottle, an electric pad, or any other form of mechanical heating device to your extremities.

6. Wear properly fitting shoes and be particularly careful that they are not too tight Use shoes made of soft leather.

7. Cut your toenails in a very good light and only after your feet have been soaked in warm water and cleansed thoroughly. Cut the toenails straight across Do not cut down into the corners of the nails. If your feet are cared for by a chiropodist, be sure to tell him about your difficulties.

8. Do not cut your corns or callouses. Never use corn plasters or corn medicine. Instead take the pressure of your shoes off corns, bunions, or callouses, by using pads or wearing larger shoes

9. Do not use circular garters.

10 Do not use strong antiseptic drugs on your feet, particularly tincture of iodine, Lysol, or carbolic acid.

11. Seek medical care at the first signs of a blister, infection of the toes, ingrowing toenails, or trouble with bunions, corns, or callouses.

12. Have some member of your family examine your feet at least once a week for blisters, sores, or other wounds.

13 Avoid getting athlete's foot. If it occurs, be very careful how you treat it. Seek your doctor's advice on the matter.

ARTERIOSCLEROSIS OBLITERANS

With the progressive extension of life expectancy, especially in the case of diabetic patients, an increase in the incidence of arteriosclerosis obliterans can be anticipated. Even at present, this disease is by far the most common of the occlusive arterial disorders

Pathogenesis. Although a number of views have been expressed regarding the causative agent in arteriosclerosis obliterans, none has been universally adopted. The opinion that has recently been exposed to experimental study suggests that an abnormal metabolism of fat and other lipids is responsible for the formation of atheromatous plaques (Gofman et al 1950a). Abnormal vascularization of the arterial wall has also been suggested as a possible factor in the production of these lesions (Leary, 1938, Wartman). Another view is that atherosclerosis results from the prolonged stress and strain to which arteries are subjected during the life of the individual, i.e.,

that it is a reflection of the natural aging process

Clinical Picture and Course. SYMPTOMS Not infrequently arteriosclerosis obliterans may exist for a long time before symptoms appear. This is due to the fact that the occlusive process generally progresses at such a slow pace that sufficient time exists for the formation of an adequate collateral circulation. Only when there is an acceleration of the rate of occlusion of main vessels or a reduction in the efficiency of the secondary circulation will the patient begin to experience the pain in the extremities which is typical of intermittent claudication Rest pain is also a common complaint; this is due to a reduced blood supply to the peripheral nerves With the onset of ulceration or gangrene, almost continuous pain may be experienced in the vicinity of the lesion

SIGNS. The objective findings in arteriosclerosis obliterans are similar in all regards to those observed in thromboangiitis obliterans, namely, *absent or reduced pulsations in the main vessels of the foot and leg*, absent or reduced oscillometric readings at the various levels on the leg and thigh, and abnormal color changes in the horizontal, elevated, and *dependent* positions Generally the feet are *dry* and *cold* rather than wet and cold, as they are in thromboangiitis obliterans.

Spontaneous trophic changes usually occur in the most distal portions of the limb, the toes and the heel (Fig. 15-19), although trauma to any part of the limb may precipitate the formation of an ulcer. In diabetic patients, secondary infection frequently plays a role in the further progression of the ulcerative or gangrenous process (Fig 15-19B).

Differential Diagnosis. The main difficulty encountered in the differential diagnosis of arteriosclerosis obliterans is its similarity to thromboangiitis obliterans. However, there are certain points which are helpful in making the differentiation, among them is the age of the patient at the time of onset of the condition. Arteriosclerosis obliterans usually begins in persons between the ages of 45 and 70 years, in diabetics, however, it may occur prematurely. In contrast, thromboangiitis obliterans

Fig. 15-19 *Trophic changes in arteriosclerosis obliterans* A. Involvement of great toe and adjoining portion of foot, ultimately *requiring* a supracondylar amputation B Gangrene and infection in a patient with associated diabetes mellitus C Rapidly spreading gangrene

has its inception in relatively younger individuals, 16 to 40 years of age. This disorder is invariably present in people who smoke, a relationship which is not necessarily noted in arteriosclerosis obliterans Furthermore, as has been mentioned, a history of superficial migratory thrombophlebitis can be elicited in somewhat less than half the cases of Buerger's disease, in contrast, arteriosclerosis obliterans is never associated with pathological changes of the veins

Calcification of the blood vessels (Monckeberg sclerosis), as determined by soft-tissue x-ray technique, is not noted in thromboangiitis obliterans, while it may be present in arteriosclerosis obliterans. Furthermore, in the latter condition, there may be signs of generalized arteriosclerosis, such as coronary insufficiency, arteriosclerotic changes in the retinal vessels, and nephrosclerosis. Such abnormalities do not exist in uncomplicated cases of thromboangiitis obliterans Finally, the pathological process in thromboangiitis obliterans may affect the arteries in the upper extremities (Fig. 15-18) much more often than is the case in arteriosclerosis obliterans.

Arteriography has also been utilized in differentiating between the two conditions. In arteriosclerosis obliterans, the arteries demonstrate irregular and eccentric filling defects and segments of complete occlusion (Fig. 15-20). Visualization of the vessels below the block is frequently observed, as a result of the movement of contrast material through the diffuse network of collateral channels generally found bridging the obstructed portion of artery. In contrast, in thromboangiitis obliterans, the vessels show narrowing but not the filling defects,

Fig. 15-20. Arteriography in arteriosclerosis obliterans. A Segmental thrombosis of femoral artery, showing bridging collateral channels and filling distally. Deep femoral artery is patent. B. Block of the femoral artery close to the origin of the deep femoral artery Numerous collateral vessels are noted.

although sites of complete occlusion may be present For the most part, the vessels are less tortuous than they are in arteriosclerosis obliterans.

Among the findings which are common to the two conditions is the symptom of *intermittent claudication* This complaint, which may manifest itself in the form of a sense of tiredness or fatigue, a dull ache, a sensation of tightness or compression, a cramp or a sharp pain, is always elicited by physical effort and is located in the exercising muscles Its presence indicates that there is an insufficient blood supply to take care of the markedly increased metabolic requirements of the tissues during physical stress. With cessation of effort, this situation no longer exists, with the result that now the impaired local vascular system is again adequate Consequently the pain subsides Obviously there should be no difference in the symptoms experienced on walking in either arteriosclerosis obliterans or thromboangiitis obliterans, since in both there is a reduction in the efficiency of the muscle circulation during exercise.

Rest pain is also common to the two conditions, in each case indicating the presence of an ischemic neuritis due to an impaired circulation to the peripheral nerves. Finally, the nutritional disturbances are similar in appearance, since they have a common causative agent, namely, a decrease in cutaneous blood flow.

Complications. In contrast with thromboangiitis obliterans, arteriosclerosis obliterans may be associated with several serious complications Among them are spontaneous *arterial aneurysm* and complete *arterial thrombosis* The latter is usually superimposed upon a gradual occlusion of an artery and may have little deleterious effect, provided the previous prolonged state of chronic hypoxia has acted as an effective stimulus for the production of an adequate collateral circulation. In the absence of such a response, complete occlusion of a critical artery may be followed by the appearance of nutritional changes (Fig. 15-21B).

Fig. 15-21. A Gangrene of foot and adjoin... aneurysm of ... arte... men... Hoeber, 1956) ...son Diagnosis and Treat-

The formation of an arterial aneurysm in arteriosclerosis obliterans occurs as a result of the weakening of the medial coats of the affected segment of vessel This type of lesion is observed more frequently in the popliteal artery than in any other vessel in the limb while involvement of the femoral artery is next in frequency. The condition is diagnosed on the basis of the presence of a *pulsating mass;* a thrill and bruit over the lesion are rather inconstant findings. A serious consequence of an arterial aneurysm is the liberation of small emboli from the clotted material, which may enter the blood stream and occlude distal vessels. Another complication is spontaneous acute thrombosis of the lesion, causing occlusion of the portion of the artery from which it arises (Fig. 15-21A). Rupture and hemorrhage of the aneurysm may place the patient's life in jeopardy

Prognosis. The prognosis in arteriosclerosis obliterans depends in great part upon the degree of simultaneous involvement of vital organs elsewhere in the body, rather than upon the changes in the extremities alone. Since the pathologic process in the blood vessels of the limbs is progressive, the appearance of nutritional disturbances depends upon the efficiency of the collateral circulation. If the latter continues to grow at a rate which is sufficient to offset the slow occlusion taking place in a main arterial trunk, then ulcers or gangrene will not occur Of course, if the existing equilibrium is destroyed, as by trauma to the extremity, then they may appear. The presence of diabetes may contribute to the gravity of the situation because of its deleterious effect upon the resistance of tissues to infection

Treatment. The regimen outlined above for the local treatment of the extremities of patients with thromboangiitis obliterans applies equally well to individuals with arteriosclerosis obliterans. This is also true for the sections on physical activity and treatment of ulcerative or gangrenous lesions.

With regard to *tobacco smoking*, the evidence that this habit has a detrimental effect upon patients with arteriosclerosis obliterans and causes progression of the occlusive process is not as clear-cut as in the case of thromboangiitis obliterans. Nevertheless, it is still advisable for a patient with arteriosclerosis obliterans to abstain from it, on the basis that smoking is a potent vasoconstricting stimulus which affects the cutaneous circulation, thus decreasing the nourishment to the skin

ARTERIAL EMBOLISM

Sudden embolic occlusion of a critical artery in the extremities is a real emergency, and therefore its early clinical recognition is essential in order to institute proper therapy immediately.

Origin. Arterial *emboli* may arise in a number of sites, the most common being a fibrillating left atrium. Even in the absence of atrial fibrillation, thrombi may form in this chamber if it has become dilated as the result of some disease. The next most common site is a mural thrombus in the left ventricle, following a myocardial infarction (Fig 15-22A). Other, less frequent, sources include a mural thrombus superimposed upon an arteriosclerotic plaque in the abdominal aorta, an aneurysm of the aorta or a main branch thereof, or valve cusps made friable by bacterial endocarditis Emboli generally lodge at the point of bifurcation of a vessel (Fig 15-22B) or where its lumen suddenly narrows.

Pathogenesis. When an artery is suddenly occluded by an embolus, blood flow distal to the occlusion ceases. At the same time the involved vessel segment acts as an irritable focus to initiate vasospasm of the unaffected collateral channels in the limb, thus further aggravating the state of hypoxia of the tissues As a result, viability may be lost and nutritional disturbances may appear.

Clinical Picture. SYMPTOMS. The initial complaint following occlusion of an artery is pain in the distal portion of the limb. This may be sharp or dull, but is usually quite severe. Various symptoms indicating ischemia of nerve structures may be experienced, such as *paresthesias* in the digits, a sensation of *numbness* or "walking on a block of wood," and inability to perform voluntary movements of the digits Associated with these complaints may be symptoms at the level of the occlusion, which are usually of short duration.

SIGNS The findings associated with sudden occlusion of a critical artery are frequently quite typical and are the result of the markedly impaired arterial circulation. The distal tissues are either *pale* in color, because of absence of blood in the subpapillary venous

plexus, or *mottled*, due to trapping of blood in some of the cutaneous venules or veins. Skin temperature is low and the superficial veins are *collapsed*. A neurologic examination generally reveals a stocking-glove type of anesthesia or hypesthesia, with *inability to move the digits.* Pulsations and oscillometric readings are absent below the occlusion and somewhat reduced or at times increased above this site.

Course and Complications. Following arterial embolism, either the circulation through the collateral vessels gradually improves, permitting the distal tissues to remain viable, or the prolonged period of hypoxia results in the appearance of *gangrene* (Fig. 15-23). The latter development is generally followed by amputation of the limb, unless the process is limited to a digit or digits and does not affect the adjoining *portion of the extremity. If irreversible* signs of destruction of tissue do not appear in the first 3 or 4 days after the onset of the condition, there is a good possibility that the viability of the limb will be maintained. However, if no attempt is made to prevent propagation of the clot, progressive occlusion of collateral vessels may cause the appearance of *nu-*

Fig. 15-22. A Mural thrombus in left ventricle, following a myocardial infarction, responsible for embolic phenomena in the left lower extremity. B Embolus at the bifurcation of the left common iliac artery, with propagation into the external and internal iliac arteries. (From Abramson, Diagnosis and Treatment of Peripheral Vascular Disorders. Hoeber, 1956.)

tritional disturbances later in the course of the disease.

Diagnosis. The diagnosis of an arterial embolism must be seriously considered whenever a marked impairment of arterial circulation to a limb appears suddenly in a patient who has previously had a normal vascular tree but is a potential candidate for thrombus formation. To initiate proper treatment, it is necessary not only to recognize the disorder in its early stages, but also to determine the exact location of the embolus. For this purpose, oscillometric studies and palpation of pulsations are essential; the examiner must keep in mind the usual locations for lodgment of the clots. At times the superimposed vasospasm may lead to erroneous conclusions and, when this possibility exists, vasomotor tonus should be removed by the use of paravertebral sympathetic, epidural, or spinal block, and the clinical findings then reevaluated.

The one entity which is difficult to differentiate from arterial embolism is arterial thrombosis and, in some instances, differentiation is impossible. Important data are a history of intermittent claudication and the previous existence of signs of impaired arterial circulation in the limb, as well as the absence of a possible site for the origin of emboli, in the case of arterial thrombosis.

Prognosis. Once the acute phase has subsided and death of tissue has not occurred, the immediate prognosis for the viability of the limb is good. Generally the collateral circulation becomes more efficient with time and the nutritional state of the skin approaches normal However, if the muscles have been left with an impaired arterial circulation, the patient may suffer from intermittent claudication

The long-range prognosis in arterial embolism depends on whether or not the cause for the original episode still operates. If it does, the possibility of recurrence of this condition in other parts of the body, including the brain, should be kept in mind. The outlook will then depend upon which vessels are occluded.

Treatment. Once the diagnosis of arterial embolism is made, a rapid-acting anticoagulant like *heparin* should immediately be given intravenously to prevent propagation of the thrombotic process distally and into the collateral vessels. The next step is to prepare the patient for an *embolectomy*, provided a critical artery is occluded and the site of embolism can be accurately determined. Lodgment of an embolus in the aortic bifurcation, the common and external iliac arteries, and the femoral and the popliteal arteries in most instances necessitates immediate embolectomy. On the other hand, there appears to be no need to remove emboli from the radial, ulnar, posterior tibial, and dorsalis pedis arteries, and this procedure is rarely carried out in the case of the brachial artery above its bifurcation.

Following embolectomy, *anticoagulant therapy* should be continued, substituting a slow-acting drug like *Dicumarol* for heparin The limb should be covered with cotton dressings to preserve its own heat, but neither heat nor cold should be applied locally. Furthermore, the limb should be left in the horizontal position and not elevated or placed in dependency. This type of regimen is also used in the case of the patient not subjected to embolectomy.

With regard to the proper approach for preventing further embolic episodes, no unanimity exists. It has been suggested that the patient remain on anticoagulant therapy for the rest

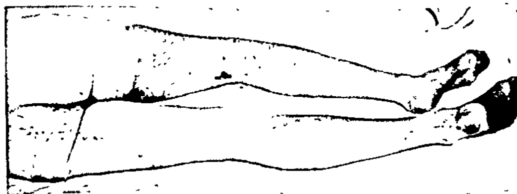

Fig. 15-23. Saddle embolus at bifurcation of aorta, causing gangrene of both lower extremities. (From Abramson. *Diagnosis and Treatment of Peripheral Vascular Disorders.* Hoeber, 1956.)

of his life. However, it is realized that in many instances such a course is impracticable. Furthermore, it is usually difficult to maintain continuously the necessary reduction in prothrombin activity through the unsatisfactory type of medical supervision available with home therapy. In the case of mitral stenosis, mitral commissurotomy and atrial appendectomy have been utilized to reduce the possibility of thrombus formation in the left atrium, but the number of cases studied up to the present has been insufficient to determine whether or not such a procedure has merit.

POLYARTERITIS (PANARTERITIS, PERIARTERITIS) NODOSA

Polyarteritis nodosa is a generalized vascular disease, principally affecting medium-sized arteries It is considered to fall within the category of "collagen vascular disorders."

Causative Factors. The cause of polyarteritis nodosa has not been determined, although several possibilities have been suggested, among them the factor of hypersensitivity. In favor of this view are certain experimental studies in which lesions typical of polyarteritis nodosa were produced by the injection of various antigens into sensitive animals (Rich and Gregory). Further evidence consists of the correlation that has been noted between polyarteritis nodosa and allergic phenomena of various types. However, the possibility has not been excluded that a hypersensitivity angiitis exists, which is similar to but not identical with polyarteritis nodosa (Churg and Strauss). Psychogenic influences acting through the adrenal cortex have also been proposed as a possible etiologic agent.

Clinical Picture. SYSTEMIC RESPONSE Since polyarteritis nodosa is a widespread disease, the symptoms are generally quite diverse. A low-grade, irregular and recurrent *fever* is frequently noted at some time in the course of the disease This is usually associated with such systemic responses as chills, malaise, prostration, and changes in the peripheral blood indicating the presence of some type of inflammatory process.

CHANGES IN THE LIMBS In the extremities, polyarteritis nodosa may be manifested by involvement of several different types of tissues. There may be ischemic ulcerations, due to thrombosis of cutaneous arterioles, or aneurysmal dilatations of the main arteries, taking the form of *subcutaneous nodules* along the course of the vessels. Nonspecific skin lesions may also be present. The peripheral nerves may be affected, producing symptoms and signs resembling a polyneuritis. These consist of numbness and tingling, paresis of the extensor muscles of the wrist, and wrist drop, similar types of change in the lower extremities, and some impairment of the perception of vibration and the sense of touch. Finally, there may be changes in the musculoskeletal system, in the form of fibrillation and atrophy of voluntary muscles, associated with pain, tenderness, and weakness.

INVOLVEMENT OF OTHER PORTIONS OF THE BODY. Most of the vital organs may be affected by the disease process. Pathologic changes in the *vessels of the brain* may produce atypical hemiplegia and cerebellar symptoms and signs. Convulsions and findings suggesting meningeal irritation may also be present. When the *kidneys* are affected, hypertension generally follows In some instances, renal insufficiency and even uremia may occur. With involvement of the *heart*, dyspnea, palpitation, and precordial pain may appear. Pathological changes in the *gastrointestinal tract* are manifested in the form of anorexia, vomiting, and weight loss, and the more serious complication of mesenteric artery thrombosis. The presence of a cough, pain in the chest, and asthmatic attacks may indicate alterations in the *pulmonary arteries*. Other findings indicative of lung involvement are pleuritis, bronchiectasis, and atelectasis.

Laboratory Data. A common finding in polyarteritis nodosa is the presence in the urine of albumin, blood, and various types of casts (red-blood-cell casts, oval fat bodies, fatty and waxy casts, and broad casts). Also of diagnostic importance are the changes in the peripheral blood. These consist of a *leucocytosis*, sometimes to as high as 50,000/mm³, and an *eosinophilia*. However, the absence of the latter does not rule out the possibility of polyarteritis nodosa Actually, it is necessary to examine numerous blood samples before concluding that this type of abnormality is not present. If the eosinophilia continues to increase, it can be interpreted as indicating activity of the disease. A secondary anemia and an elevated sedimentation rate may be associated with the changes in the white blood cells

tritional disturbances later in the course of the disease.

Diagnosis. The diagnosis of an arterial embolism must be seriously considered whenever a marked impairment of arterial circulation to a limb appears suddenly in a patient who has previously had a normal vascular tree but is a potential candidate for thrombus formation. To initiate proper treatment, it is necessary not only to recognize the disorder in its early stages, but also to determine the exact location of the embolus. For this purpose, oscillometric studies and palpation of pulsations are essential; the examiner must keep in mind the usual locations for lodgment of the clots. At times the superimposed vasospasm may lead to erroneous conclusions and, when this possibility exists, vasomotor tonus should be removed by the use of paravertebral sympathetic, epidural, or spinal block, and the clinical findings then reevaluated.

The one entity which is difficult to differentiate from arterial embolism is arterial thrombosis and, in some instances, differentiation is impossible. Important data are a history of intermittent claudication and the previous existence of signs of impaired arterial circulation in the limb, as well as the absence of a possible site for the origin of emboli, in the case of arterial thrombosis.

Prognosis. Once the acute phase has subsided and death of tissue has not occurred, the immediate prognosis for the viability of the limb is good. Generally the collateral circulation becomes more efficient with time and the nutritional state of the skin approaches normal. However, if the muscles have been left with an impaired arterial circulation, the patient may suffer from intermittent claudication

The long-range prognosis in arterial embolism depends on whether or not the cause for the original episode still operates. If it does, the possibility of recurrence of this condition in other parts of the body, including the brain, should be kept in mind. The outlook will then depend upon which vessels are occluded.

Treatment. Once the diagnosis of arterial embolism is made, a rapid-acting anticoagulant like *heparin* should immediately be given intravenously to prevent propagation of the thrombotic process distally and into the collateral vessels. The next step is to prepare the patient for an *embolectomy*, provided a critical artery is occluded and the site of embolism can be accurately determined. Lodgment of an embolus in the aortic bifurcation, the common and external iliac arteries, and the femoral and the popliteal arteries in most instances necessitates immediate embolectomy. On the other hand, there appears to be no need to remove emboli from the radial, ulnar, posterior tibial, and dorsalis pedis arteries, and this procedure is rarely carried out in the case of the brachial artery above its bifurcation.

Following embolectomy, *anticoagulant therapy* should be continued, substituting a slow-acting drug like *Dicumarol* for heparin. The limb should be covered with cotton dressings to preserve its own heat, but neither heat nor cold should be applied locally. Furthermore, the limb should be left in the horizontal position and not elevated or placed in dependency. This type of regimen is also used in the case of the patient not subjected to embolectomy.

With regard to the proper approach for preventing further embolic episodes, no unanimity exists. It has been suggested that the patient remain on anticoagulant therapy for the rest

mild emotional strain. In many instances, however, the severity of the condition remains unchanged.

The sequence typical of the color changes is pallor during the period in which the exciting stimulus operates, cyanosis, rubor, and then a return to the normal color. However, it is not necessary to observe all of the abnormalities in order to make the diagnosis. For example, cyanosis may be the initiating color, while pallor may be absent, or pallor may be followed by rubor without the appearance of cyanosis. In some instances, pallor or cyanosis may be replaced by a normal color without rubor intervening. To be able to make the diagnosis, either pallor or cyanosis should be noted initially.

It is necessary to emphasize that the color change in Raynaud's disease is limited to the digits and that it does not extend on to the adjoining part of the hand or foot. It generally is noticed first in the tips and later in the more proximal portion of the phalanges. Early in the disease, there may be a unilateral color change, but eventually bilateral distribution, with symmetrical digital involvement, is noted. At no time is there a reduction in or absence of pulsations in the main artery to the limb, and the results of various tests for arterial efficiency are generally normal.

Mild trophic changes may appear in the involved digits, such as abnormal growth or brittleness of the nails, loss of subcutaneous tissue, and calcium deposits in the finger tips. At times, there may be more severe abnormalities such as atrophic arthritis and sclerodermatous alterations in the skin (*sclerodactylia*). Superficial ulceration and gangrene of the tips of the digits may also occur (Fig 15-24). The excruciating burning sensation frequently associated with these lesions is usually much out of proportion to their apparent severity.

PROGNOSIS. It is important to reassure the patient with Raynaud's disease that, although the condition may cause great inconvenience at times and may even interfere with his daily activity, it is still a relatively benign disorder. The fact that the attacks can be controlled to some extent by eliminating the agents which initiate them is in contrast with the more serious occlusive arterial vascular disorders, in which progression of the pathological state frequently occurs regardless of what approach is utilized as treatment. In those instances of Raynaud's disease in which superficial ulceration or gangrene is noted, the lesions are usually limited to the distal portion of the digits and rarely require amputation of a finger.

TREATMENT *Protection from Noxious Stimuli or Trauma.* One of the most important steps in the treatment of Raynaud's disease is the reduction or elimination of those conditions which initiate the digital spasm. Because cold is very potent in this regard, it is necessary to decrease the periods of exposure of the body, and particularly the extremities, to this agent to a minimum. The hand warmer used by sportsmen is of value in preventing attacks while the patient is outdoors. Mittens should be worn in preference to gloves since they produce less constricting effect on the digits.

Because of the proved vasoconstricting ef- [illegible] tween smoking and the progression of this disorder, although it has been noted in the case

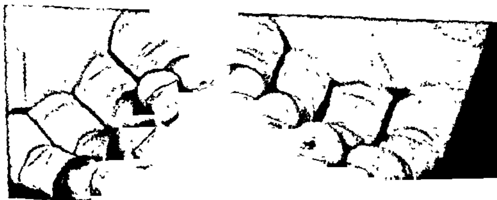

Fig 15-24 Small ulceration of finger tips in Raynaud's disease

Since polyarteritis nodosa may mimic a great number of systemic disorders, it may be necessary in many instances to resort to a *biopsy* study of a subcutaneous nodule or a section of skeletal muscle before arriving at the proper diagnosis. In order to obtain definitive information by such a means, however, the specimen of muscle should be removed from a site in which pain and tenderness are experienced.

Prognosis. The outlook in polyarteritis nodosa is grave, with the usual acute case going on to total debility and death in a period of from several weeks to several months. Nevertheless, it is necessary to point out that there may be exacerbations and remissions, with healing occurring in some instances. It is also possible that there are mild cases in which the diagnosis is infrequently made. Death in polyarteritis nodosa generally results from congestive heart failure or renal insufficiency and, less frequently, from hemorrhage due either to the rupture of an aneurysm or to necrosis of critical organs.

Treatment. Therapy in polyarteritis nodosa has, for the most part, been symptomatic and supportive, involving the administration of proper diet, the use of antibiotics for intercurrent infections, the control of congestive heart failure, and the treatment of painful muscles and joints with orthopedic appliances. Recently, however, *cortisone* and *corticotropin (ACTH)* have been utilized, with prompt relief of symptoms and disappearance of fever in many instances. However, relapses have generally occurred with termination of the medication. At present, it is still too early to give the final evaluation of this type of therapy, although it appears to hold promise

SPECIAL VASCULAR SYNDROMES

Raynaud's Disease. Raynaud's disease is a functional or vasospastic vascular disorder, which is typified by episodes of color changes in the fingers and toes, initiated by exposure to cold or by emotional excitation In order to make this diagnosis, it is necessary to demonstrate that no apparent causative factor exists. If one does, then the condition is considered to fall within the category of *Raynaud's syndrome* or *phenomenon* To support the diagnosis of Raynaud's disease, the episodes of color changes should be present for at least 2 years without the appearance of any of the signs or symptoms of an occlusive arterial vascular disorder.

PATHOGENESIS. Typically, the initial color change is *pallor* of the digits, produced by spasm of the digital arteries This may be followed by *cyanosis,* which is probably due either to a slow flow of blood through the capillaries, as a result of intermittent removal of spasm from the digital arteries, or to simultaneous spasm of digital veins, interfering with the movement of blood out of the tissues. As a consequence, there is a greater opportunity for the removal of oxygen from the blood as it passes through the capillary bed, so that the quantity of reduced hemoglobin in the subpapillary venous plexuses is increased, resulting in cyanosis of the skin. *Rubor,* which is generally the final color change, occurs after spasm of the digital arteries abates. It is a manifestation of the stage of reactive hyperemia which follows a period of lack of circulation to tissues.

The cause for the initiation of spasm of the digital arteries is not clear. It has been suggested (Heinbecker and Bishop; Hyndman and Wolkin) that the vessels themselves have an inherent increased sensitivity to cold, or that there is an abnormality in the innervation of the sympathetic nervous system (Adson; Simpson et al).

Since Raynaud's disease is a functional vascular disorder, it is generally not associated with permanent alterations in the digital arteries However, if the condition has existed for a long time or if various types of nutritional disturbances are present, histologic examination may reveal intimal hyperplasia and other pathologic changes in the terminal branches (Lewis, 1938).

CLINICAL PICTURE. Raynaud's disease is seen predominantly in young women, although it does occur on occasion in young men (Hines and Christensen, Abramson and Shumacker). Generally associated with the episode of pallor or cyanosis is a sense of coldness, numbness, or tightness in the involved digits. As the digital spasm wears off and the circulation is reestablished, paresthesias or burning or throbbing sensations may be experienced in the fingers. With progression of the condition, the attacks of color change may become more frequent and be elicited by even a slight reduction in the temperature of the environment or by

tree and characterized by periods of very severe burning sensations in the extremities and increased cutaneous temperature and rubor of the involved portions The attack is generally initiated by a rise in the environmental or body temperature. Although there are some workers (Lewis, 1933) who believe that this condition is a symptom complex, existing in many disorders, there appears to be sufficient evidence to warrant utilizing the term "primary erythromelalgia" for certain cases to denote a definite clinical entity

PATHOGENESIS The typical findings are probably related to the associated increase in local circulation invariably noted during an attack. However, there are probably other factors contributing to the pathogenesis of the condition, since an increase in peripheral blood flow in a normal limb, equal to that observed in erythromelalgia, does not ordinarily induce a burning sensation.

CLINICAL PICTURE AND DIAGNOSIS An important clue in the diagnosis of erythromelalgia is a history detailing the onset of the characteristic signs and symptoms after the extremity has been subjected to a high environmental temperature or to exercise. It is of interest that a definite elevation of temperature is necessary to precipitate the attacks and that below this point they are absent. In determining whether erythromelalgia exists, it may be necessary to attempt to initiate the burning sensation by raising the environmental temperature beyond the critical level

In "primary erythromelalgia" all the results of tests for circulatory efficiency are normal During an attack, the amplitude of the peripheral pulses and the oscillometric readings may be greater than normal In the differential diagnosis of the disorder, other conditions which could conceivably be responsible for the typical severe burning sensation in the extremities must be excluded Among them are polycythemia vera, thromboangiitis obliterans, peripheral neuritis associated with diabetes, pernicious anemia, and pantothenic acid deficiency.

PROGNOSIS Although primary erythromelalgia may produce considerable discomfort and even disability if the attacks are frequent, it is never associated with any untoward effects of a serious nature

TREATMENT No specific therapy exists for primary erythromelalgia. The important approach is the elimination of the initiating agent, i e, a rise in cutaneous temperature. The feet should be exposed to a cool environment as much as possible. If the attacks are causing enough difficulty to interfere with daily activities, it may be necessary to advise the patient to move to a more moderate climate.

A treatment of value consists of an attempt to decrease the sensitivity of the cutaneous vessels to heat by placing the involved extremities in water at a temperature low enough to produce no complaints and then gradually increasing the water temperature until discomfort is elicited. By means of repeated immersions, it may be possible to accustom the limbs to the critical temperature or even levels beyond this point. As temporary measures, certain medications are valuable in reducing the severity of the symptoms. Among these are *aspirin*, *ergotamine tartrate* in combination with *belladonna*, intravenously administered *calcium gluconate*, and 1:1,000 solution of *epinephrine* administered by inhalation (Mufson). The severity of the attack can be diminished somewhat by wrapping the affected extremities in cold, wet cloths or immersing them in ice water.

Immersion Foot and Trench Foot. CAUSATIVE FACTORS. Both trench foot and immersion foot result from exposure of the lower extremities to a cold, wet environment for a relatively prolonged period of time. The degree of cold necessary to produce these conditions is generally close to 32°F. The associated moisture augments the detrimental effect of the cold, since water has a high capacity for absorbing heat and thus causes better transmission of the cold to the tissues.

Trench foot occurs in combat and results from wearing wet socks and other wet footgear for days on end. Immersion foot is the seagoing counterpart, and is found in survivors of shipwrecks who have been compelled to sit for many hours, immobile, in a crowded, open lifeboat or raft with their feet immersed in water

PATHOGENESIS The basis for the pathologic changes observed in trench foot and immersion foot is probably *vasoconstriction*, followed by prolonged *hypoxia*, resulting from exposure of the tissues to cold As a consequence, there is sufficient damage to the capillary wall to permit movement of fluid into the tissue spaces, with

of thromboangiitis obliterans. If the patient cannot abstain, at least he should make every attempt not to smoke when outdoors in the cold.

Since minor bruises or even a pinprick may be sufficient to initiate superficial ulceration, the patient must be warned to protect his digits from injury. At times it may be necessary to advise a change in the type of daily activity if the work carries with it the possibility of trauma to the extremities.

Removal of Vasomotor Tonus. Another worth-while therapeutic approach is the utilization of procedures or medications which temporarily or permanently eliminate sympathetic control over the digital arteries. Among them are the sympathetic blocking agents such as *Priscoline*, *Hydergine*, and *Dibenzyline*. These drugs cause temporary inhibition of vasomotor tonus and thus lead to a reduction in the reactivity of the peripheral vessels to cold. Whiskey and other alcoholic beverages may also have a beneficial action, particularly during an episode of digital spasm.

It is generally agreed that *sympathectomy* produces beneficial effects in Raynaud's disease through a reduction in the intensity of the vasoconstricting response to local cold and through elimination of reflex vasoconstriction initiated by distant stimuli. However, in the case of the patient with Raynaud's disease who is not suffering from nutritional disturbances, this procedure should be resorted to only when the attacks of digital color change are numerous and disabling and are limited to one or two extremities. When three or four limbs are involved, the operation is not indicated, since the resulting widespread sympathetic denervation might cause marked impairment in the efficiency of the mechanism of heat loss from the body through sweating.

In the presence of infected ulcerations or superficial gangrene of the finger tips, sympathectomy has a definite place in therapy. It will frequently cause rapid improvement in the condition even after prolonged conservative therapy has been ineffectual. However, it is necessary to point out that, once healing has occurred, recurrences of nutritional disturbances in other digits may still take place

Psychotherapy. Since emotional excitation may be a potent stimulus for the production of digital spasm, every patient with Raynaud's disease should receive a certain amount of guidance in making a mental and physical adjustment to his disability. The individual who is markedly responsive to this type of stimulus and who, as a result, suffers from nutritional disturbances, may find it necessary to seek psychiatric care.

Acrocyanosis. Acrocyanosis is another functional or vasospastic condition, characterized by a persistent, uniform, cyanotic rubor of the skin of the hands, forearms, feet, and legs. The color change is present in a warm as well as a cold environment, although it is more marked in the latter.

PATHOGENESIS. Although the underlying mechanism is not clear, it has been suggested that the cause for the color change is prolonged *arteriolar spasm*, associated with capillary and venous paralysis. The available evidence does not implicate the sympathetic nervous system Because of the resulting slowed flow through the capillary bed, a greater opportunity is afforded for the removal of oxygen by the tissues As a consequence, the blood entering the subpapillary venous plexuses contains a larger than normal quantity of reduced hemoglobin, which is responsible for the cyanotic color of the skin.

CLINICAL PICTURE. The typical alteration observed in acrocyanosis is a deep-purple color of the skin on exposure to extreme cold and a red appearance in a warm environment. The change is persistent, except for its intensity, and does not occur in the form of episodes as noted in Raynaud's disease. Furthermore, the abnormal color is not limited to the digits, but involves the entire hand or foot, as well as the adjoining portion of the limb. As in the case of Raynaud's disease, all tests of arterial circulation indicate no involvement of the main arteries.

PROGNOSIS. Acrocyanosis is associated with no sequelae of serious consequences. It, therefore, can be considered to be a relatively benign functional disorder. However, it may cause a certain amount of discomfort and disability for some individuals.

TREATMENT. The only therapy for acrocyanosis is avoidance of exposure to cold. The use of sympathetic blocking agents has been proposed but appears to have little value.

Erythromelalgia. Erythromelalgia is a functional vascular disorder affecting the arterial

tree and characterized by periods of very severe burning sensations in the extremities and increased cutaneous temperature and rubor of the involved portions. The attack is generally initiated by a rise in the environmental or body temperature Although there are some workers (Lewis, 1933) who believe that this condition is a symptom complex, existing in many disorders, there appears to be sufficient evidence to warrant utilizing the term "primary erythromelalgia" for certain cases to denote a definite clinical entity.

PATHOGENESIS The typical findings are probably related to the associated increase in local circulation invariably noted during an attack. However, there are probably other factors contributing to the pathogenesis of the condition, since an increase in peripheral blood flow in a normal limb, equal to that observed in erythromelalgia, *does not ordinarily induce a burning sensation.*

CLINICAL PICTURE AND DIAGNOSIS. An important clue in the diagnosis of erythromelalgia is a history detailing the onset of the characteristic signs and symptoms after the extremity has been subjected to a high environmental temperature or to exercise It is of interest that a definite elevation of temperature is necessary to precipitate the attacks and that below this point they are absent In determining whether erythromelalgia exists, it may be necessary to attempt to initiate the burning sensation by raising the environmental temperature beyond the critical level

In "primary erythromelalgia" all the results of tests for circulatory efficiency are normal During an attack, the amplitude of the peripheral pulses and the oscillometric readings may be greater than normal In the differential diagnosis of the disorder, other conditions which could conceivably be responsible for the typical severe burning sensation in the extremities must be excluded Among them are polycythemia vera, thromboangiitis obliterans, peripheral neuritis associated with diabetes, pernicious anemia, and pantothenic acid deficiency.

PROGNOSIS Although primary erythromelalgia may produce considerable discomfort and even disability if the attacks are frequent, it is never associated with any untoward effects of a serious nature.

TREATMENT No specific therapy exists for primary erythromelalgia. The important approach is the elimination of the initiating agent, i.e., a rise in cutaneous temperature. The feet should be exposed to a cool environment as much as possible. If the attacks are causing enough difficulty to interfere with daily activities, it may be necessary to advise the patient to move to a more moderate climate.

A treatment of value consists of an attempt to decrease the sensitivity of the cutaneous vessels to heat by placing the involved extremities in water at a temperature low enough to produce no complaints and then gradually increasing the water temperature until discomfort is elicited. By means of repeated immersions, it may be possible to accustom the limbs to the critical temperature or even levels beyond this point. As temporary measures, certain medications are valuable in reducing the severity of the symptoms. Among these are *aspirin*, *ergotamine tartrate* in combination with *belladonna*, intravenously administered *calcium gluconate*, and 1:1,000 solution of *epinephrine* administered by inhalation (Mufson). The severity of the attack can be diminished somewhat by wrapping the affected extremities in cold, wet cloths or immersing them in ice water.

Immersion Foot and Trench Foot. CAUSATIVE FACTORS. Both trench foot and immersion foot result from exposure of the lower extremities to a cold, wet environment for a relatively prolonged period of time. The degree of cold necessary to produce these conditions is generally close to 32°F The associated moisture augments the detrimental effect of the cold, since water has a high capacity for absorbing heat and thus causes better transmission of the cold to the tissues.

Trench foot occurs in combat and results from wearing wet socks and other wet footgear for days on end. Immersion foot is the seagoing counterpart, and is found in survivors of shipwrecks who have been compelled to sit for many hours, immobile, in a crowded, open lifeboat or raft with their feet immersed in water.

PATHOGENESIS The basis for the pathologic changes observed in trench foot and immersion foot is probably *vasoconstriction*, followed by prolonged *hypoxia*, resulting from exposure of the tissues to cold. As a consequence, there is sufficient damage to the capillary wall to permit movement of fluid into the tissue spaces, with

Fig. 15-25. Gangrene of feet in trench foot.

the development of *edema*. At the same time hemoconcentration and sludging of the blood occur; both of these are conducive to local thrombosis.

Another mechanism which contributes to the death of tissues is the initial hyperemic stage, during which the metabolic needs are raised, but an adequate local blood supply to satisfy them is not available. The changes observed during this period may be due either to an inflammatory reaction to cold, to vasomotor paralysis following interruption of vasoconstrictor fibers in the peripheral mixed nerves, or to direct damage to the vessel wall.

CLINICAL PICTURE Trench foot and immersion foot may be divided into several clinical stages. In the first, or prehyperemic stage, the symptoms may be of a minor degree, consisting of numbness, aching, and tingling. At this time the involved foot is initially red and later white. The arterial pulsations are reduced or absent because of the associated vasospasm

As recovery takes place, the hyperemic stage appears. Now the pulsations in the main arteries are bounding and the feet are red, hot, and dry. There may be petechial hemorrhages due to ruptured capillaries, and there may also be vesicles filled with straw-colored fluid. Superficial and deep gangrene may be noted (Fig 15-25).

In the last, or posthyperemic, stage the signs of vasodilatation gradually subside The swelling and blisters disappear, the skin temperature of the feet drops and marked sensitivity to cold is experienced. There may be hyperhidrosis, rigidity, pain in the ankles and other joints on walking, and weakness and deformities of the feet, in part due to disuse

PROGNOSIS. It is difficult to determine prognosis in trench foot and immersion foot since the question of government compensation will continue to plague the examiner and cast doubt on the authenticity of the reports obtained from the patients There is little question, however, that signs of excessive sympathetic tone will persist for many years. The patient will also continue to have a marked sensitivity to extremes of environmental temperature

TREATMENT. The question of treatment revolves around methods of preventing trench foot and immersion foot. Despite intense effort by the Army and Navy to reduce the incidence of these conditions, very little success has as yet been achieved. No shoe has been perfected which will satisfactorily prevent the feet from becoming cold and wet during combat

Initially, the active treatment should be directed at controlling the increase in metabolism that occurs during the hyperemic stage. Later, attempts should be made to counteract the atrophy of disuse and to make the patient assume a normal gait and again become ambulatory. Sympathectomy plays only a limited role in the treatment of the chronic stage of trench foot or immersion foot.

PRIMARY VARICOSITIES (VARICOSE VEINS)

Primary varicosities probably comprise one of the most common abnormalities in the category of peripheral vascular disorders, particularly among women. Because of the relative frequency of such complications as stasis dermatitis and ulceration, this condition is responsible for the loss of many productive hours from industry or household duties It therefore is of great importance to initiate appropriate treatment early in the disorder, before sequelae appear.

Causative Factors. Several factors have been proposed as possible causative agents in the production of *incompetent superficial veins* of the lower extremities One of these factors possibly is an inherent structural weakness of the valves in the affected vessels, a view which is supported by the frequent existence of a family history of varicosities Another is the hemodynamic effect of the erect position. Since there are no valves in the inferior vena cava and common iliac veins, the full hydrostatic action of the column of blood in the abdomen must normally be counteracted by the valves in the external iliac and femoral veins In the congenital absence of these structures in the latter vessels, an even greater burden of support is placed on the valve at the saphenofemoral junction It is this structure which is almost invariably affected when varicosities are present.

Other factors which may predispose to varicosities are heavy muscular work with straining at lifting, pelvic tumors, and mechanical constriction of the limb, such as produced by elastic supports, girdles, garters, and tight bandages. Obesity is an important factor, since subcutaneous fat supplies little effective support to the superficial veins. The fact that varicosities are predominantly present in females suggests that certain anatomic factors existing in this sex contribute to the production of venous stasis Among these are the broader pelvis and the increased hyperemia of the pelvic veins during puberty, menopause, menstruation, and pregnancy.

Pathogenesis. Varicosities are produced when the valves in the veins of the lower extremities become incompetent, thus allowing regurgitation of blood into the superficial venous system This may occur at the saphenofemoral junction or in the communicating or perforating vessels which join the superficial and deep venous systems at different levels in the thigh and leg Because the superficial vessels have poor support, they enlarge and become tortuous when the pressure within them rises abnormally As a consequence of the distention of the vessels, the valves become incompetent

Clinical Picture. SYMPTOMS The patient with varicosities may or may not have any symptoms Furthermore, there is not always a relationship between their severity and the degree and extent of involvement of the veins. The usual complaints consist of a *sense of heaviness* or *fullness* and *easy fatigue* in the involved limb, probably as a result of the venous stasis and increased weight of the extremity. The patient will note that the longer he stands in one position, the more marked will his symptoms become. On the other hand, elevation of the limb, and, to a lesser extent, walking, have a beneficial action. *Night cramps* are fairly common and appear to be dependent upon the amount of physical exertion undergone during the day.

SIGNS. Examination of the extremities invariably reveals the appearance of prominent, tortuous, superficial veins, which become more obvious when the patient stands (Fig 15-26). The presence of a regurgitant flow in these vessels is determined by the various tests described below.

Trendelenburg Test. This procedure, which is the one most frequently used, is of value in differentiating dilated from varicose superficial veins and also in determining whether or not incompetent communicating channels exist. The test is performed as follows:

With the patient lying on his back, the involved limb is elevated in order to empty the superficial veins and while the limb is in this position, a rubber tourniquet is applied around the thigh below the level of the fossa ovalis. The patient now stands, and within 10 sec the tourniquet is released An immediate filling *of the great saphenous vein from above downward indicates that the valve in this vessel is incompetent.* A normal response is a slow filling of the superficial veins (in about 30 sec or more) as a result of the movement of blood upward from the capillary system

The test can also be performed by maintaining the tourniquet in place with the patient in the upright position and determining the rate at which the veins fill below the level of the compression. The rapid appearance of dilated vessels when the patient stands indicates that there has been a reflux flow into them either from the small saphenous system or from incompetent communicating branches in the leg or lower thigh

Multiple Tourniquet Test This procedure, a modification of the Trendelenburg test, involves the use of four tourniquets, three applied to the thigh, so as to compress the upper, middle, and lower segments, respectively, and

one to the leg below the knee; the tourniquets are applied while the patient is lying down with his lower extremity elevated. He then assumes the upright position and the rate of venous filling below the level of the most distal tourniquet is noted. If the vessels below the knee become prominent rapidly, it can be assumed that there are incompetent communicating veins in the lower portion of the leg. If no change is noted, the most distal band is removed. Immediate filling of the superficial veins under these circumstances implies that the small saphenous vein is incompetent. In ascending order the three tourniquets on the thigh are then removed, the appearance of clusters of veins being sought after each step. If the change occurs following removal of the bands around the middle and the lower third of the thigh, it can be assumed that the venous channels in these sites, aside from the great saphenous vein, are incompetent. Sudden distention of the veins on the leg and thigh with release of the last tourniquet, on the upper third of the thigh, localizes the difficulty to the saphenofemoral junction

Percussion or Schwarz Test. This procedure is carried out by having the patient stand so as to fill the superficial veins, and then tapping the lower level of a distended vessel with a finger. The fingers of the other hand are at the same time placed over the upper segment of the vein. After determining whether or not an impulse is perceived by the examining fingers, the procedure is reversed, with the tapping being applied to the proximal portion of the vein near the fossa ovalis, and the palpating digits placed distally over the vessel Again, the desired information is whether or not an obvious impulse can be felt.

If incompetency exists, a disturbance will be initiated by the application of the blow which travels in either direction over the column of blood in the form of a wave In a vein with competent valves, proximal spread occurs to only a minor degree, while there is no distal spread

Fig. 15-26. A. and B. Primary varicosities of the greater saphenous system.

Venous Pressure Readings. The determination of the venous pressure in the foot has more experimental than clinical application, since it generally requires surgical exposure of a superficial vein on the dorsum of the foot and cannulation of a vessel by a No. 14 gage, thin-walled needle. Normally, the venous pressure reading in the foot varies with the position of the body. When the subject is lying down, it is the same as the pressure in the upper extremity (4 to 8 mm Hg). When the subject stands up, the pressure rises to a level equal to that in recumbency plus an increment representing the hydrostatic pressure of the column of blood between the heart and the point tested. The readings, therefore, vary between 70 and 100 mm Hg. When the subject is exercising, the pressure falls to 30 to 40 mm Hg, due to the pumping action of the muscles on the neighboring veins, which shunts the blood into the deep venous system and out of the limb.

In the presence of varicosities, the readings in recumbency are generally higher than those in normal individuals, while on standing they are approximately the same. With exercise, the drop ordinarily observed does not occur because blood is regurgitated from the deep venous system into the superficial veins. If a tourniquet has been previously applied to the thigh in order to prevent retrograde flow, walking will reduce the pressure to normal levels.

Complications. The complications of varicosities are generally due to the associated venous stasis, a chronic pooling of blood in the involved superficial veins, resulting in their overdistention. As a consequence, certain changes will take place in the skin: *edema*, first pitting and eventually nonpitting, *pigmentation*, stasis dermatitis, chronic indurated *cellulitis*, and finally *ulceration*. These changes are similar to those observed in the postphlebitic syndrome (Fig. 15-27). Ulceration has definite economic implications because if it has developed once it frequently recurs and thus renders the patient a semi-invalid, incapable of working for weeks and even months during each attack.

Prognosis. The outlook for the patient with varicosities depends to a great extent upon whether or not the above-mentioned complications can be prevented or, if they are present, whether they can be controlled and eliminated. It must be pointed out that, although temporarily disabling, they are never associated with immediate danger to life.

Treatment. MEDICAL. Medical treatment is of limited value in the control of primary varicosities, for the various procedures at best alleviate rather than cure the disorder. However, under certain circumstances, it is necessary to utilize one or several of them, either as a temporary measure or permanently, if there are contraindications to surgery. Conditions for which medical methods have been suggested are pregnancy, nonsymptomatic minor varicosities, and varicosities associated with local arterial impairment. With varicosities which have recurred after surgery and in treating certain psychoneurotic individuals, it is also probably better to use a medical approach. Finally, there is some question regarding the advisability of surgery for elderly and obese patients.

Elastic Support. The medical treatment of varicosities consists for the most part of the use of some type of elastic compression of the superficial veins. This can be accomplished through the application of elastic stockings or by means of elastic bandages.

Sclerosing Technique. The intravenous injection of a sclerosing agent has a limited use, except when it supplements surgical therapy. Only patients showing minor involvement are satisfactorily treated in this fashion. The procedure in no way reduces the reflux of blood occurring in the proximal portion of the extremity; as a result, while some vessels are obliterated by the sclerosing solution, others become varicose because of the shunting of blood into them. Another reason for the limited use of the injection technique is that recanalization of the thrombosed veins usually takes place because of the constant back pressure due to the retrograde flow of blood.

SURGICAL. The surgical approach is in most instances the proper treatment of varicosities. A number of methods have been utilized but as yet there is no unanimity as to which is the most effective. However, in recent years there has been a tendency to depend more and more upon high ligation of the great saphenous vein and extirpation of a part or all of this vessel by means of a stripper. Other methods which have been used are (1) high ligation of

the great saphenous vein at its junction with the femoral vein; (2) high ligation of the great saphenous vein, followed by retrograde injection of a sclerosing agent into the distal portion of the vessel; and (3) high ligation of the *great saphenous vein at its junction with the femoral vein*, plus multiple ligations and divisions of the vessel along its course.

SUPERFICIAL AND DEEP THROMBOPHLEBITIS

Inflammatory involvement (together with secondary thrombosis) of the walls of the veins in the extremities, is a relatively frequent occurrence, particularly in the case of the superficial venous system. Rarely is thrombosis present without the subsequent appearance of a phlebitic process The clinical picture will vary markedly depending upon whether the *superficial or deep set of veins is involved*

Etiology. A number of physiologic and pathologic states are conducive to the initiation of venous thrombosis Among these are venous stasis, direct trauma to the vessel wall, and alterations in the coagulability of the blood, caused by either injury to tissues elsewhere in the body or changes in the formed elements in the blood stream.

Fig. 15-27. Postphlebitic syndrome A. Chronic indurated cellulitis, with marked browniness and fibrotic reaction in skin. B. Stasis ulceration in usual site on medial aspect of ankle. C. Brown pigmentation and hyperkeratosis following prolonged venous stasis.

VENOUS STASIS This is one of the most important conditions contributing to intravascular clotting It may be initiated by physical inactivity, immobilization of the limb, the application of tight abdominal dressings, the assumption of Fowler's position, the use of pillows placed under the knees, and increased vasomotor tonus present during and immediately after an operative procedure. All of these factors interfere with venous return and cause pooling of blood in the veins of the lower extremities A similar situation may occur in severe congestive heart failure and during pregnancy.

INJURY TO THE INTIMA OF A VEIN. This type of change may result from crushing injuries to the limb, fractures, deep wounds, operative procedures in the pelvis, and the intravenous administration of irritating drugs. Trauma to veins may also occur following sudden and severe (or moderate but repeated) muscular contractions in the lower extremities Prolonged pressure of the weight of the leg on the calf muscles may likewise cause intimal damage. Malignant invasion of veins can produce the same type of change.

INCREASE IN THE COAGULABILITY OF THE BLOOD Such an abnormality may result from destruction of tissue elsewhere in the body, as in the case of a surgical procedure, extensive burns, a delivery, or infection The causative factors are probably a greater viscosity and an elevation of the fibrinogen content of the plasma In visceral carcinoma, which may be associated with venous thrombosis—particularly in the lower extremities—the cause is again most likely some type of change in the coagulation mechanism, possibly related to destruction of tissue by cancerous infiltration

Among the hematologic conditions characterized by a tendency toward blood coagulation is *polycythemia*, in which the responsible factor is the greater viscosity of the blood resulting from the increased number of red blood cells A similar type of response may be noted in severe anemia as a result of the expression of large quantities of thrombin-rich serum by a greater-than-normal clot retraction

Pathogenesis Intravascular thrombosis begins with the adhesion of thrombocytes to the intima of a blood vessel at a point where the endothelium has been injured, this is followed by the formation of platelet thrombi. The latter are then lysed and thrombin is produced; finally a reticulum of fibrin is deposited. With retraction of the clot, a serum rich in thrombin is expressed, thus causing further local clotting and propagation of the process. Eventually the thrombus fills the lumen of the vessel and causes complete occlusion.

Clinical Picture. SUPERFICIAL THROMBOPHLEBITIS *Symptoms.* In the case of superficial thrombophlebitis, the symptoms are generally minimal and consist of tenderness in the area of involvement. If this happens to be located near a portion of the extremity which is moved on walking, then pain will be felt. No systemic symptoms are experienced

Signs Since thrombosis of a superficial vein does not interfere with venous outflow, there are no signs of increased venous pressure and hence no swelling, except locally in the immediate vicinity of the affected vein. This area generally manifests signs of inflammation, such as redness and increased cutaneous temperature. Palpation of the area reveals the presence of a firm linear mass under the skin, representing the thrombosed vessel and some perivenous inflammation (Fig. 15-27). The lesion may be 1 or 2 in. long or may involve a considerable portion of the main superficial venous channels and their tributaries. Systemic manifestations are not noted.

THROMBOSIS OF DEEP VEINS. The clinical picture associated with thrombosis of the deep veins of the lower extremities will vary markedly, depending upon the importance and location of the occluded vessels and their role in the removal of blood from the limb. If the occlusion involves the venous plexus in the muscles of the calf and plantar portion of the foot (*phlebothrombosis*), little interference with venous return occurs, and hence the physical findings are minimal On the other hand, when a main venous channel, e g, the popliteal or iliofemoral vein, is occluded (*acute deep thrombophlebitis*), the clinical picture is quite typical and apparent.

Symptoms of Phlebothrombosis In this condition, the complaints are rather nonspecific. The patient may be apprehensive and restless, experiencing ill-defined sensations. Locally there may be an ache or a cramplike pain in the calf at rest, with tenderness in this site and in the plantar portion of the foot.

Signs of Phlebothrombosis. One of the more important objective findings in phlebothrombosis is pain in the calf, elicited on dorsiflexion of the foot (*positive Homans' sign*). The calf muscles may be tense or spastic, and at times an indefinite mass may be palpated between the bellies of the gastrocnemius muscle. There may also be a slight increase in the circumference of the calf, determined only by measurement. No obvious swelling is present. Among the systemic signs are slight and simultaneous increases in body temperature and pulse and respiratory rates, without any apparent cause for such changes.

Symptoms of Acute Deep Thrombophlebitis. Typical complaints in this condition are *pain* and *tenderness* along the course of the involved vessel and in the groin. Tenderness is also generally present in Scarpa's triangle. The patient may manifest constitutional responses in the form of malaise and loss of appetite.

Signs of Acute Deep Thrombophlebitis. Because a main venous channel is occluded in acute deep thrombophlebitis, there is marked interference with venous outflow, manifested in the early appearance of *swelling* of the extremity, most obviously in the distal portion (Fig. 15-28). If massive, the edema may resist pitting, but later this type of response may be elicited as the activity of the pathological process diminishes. A common associated finding is the presence of *prominent*

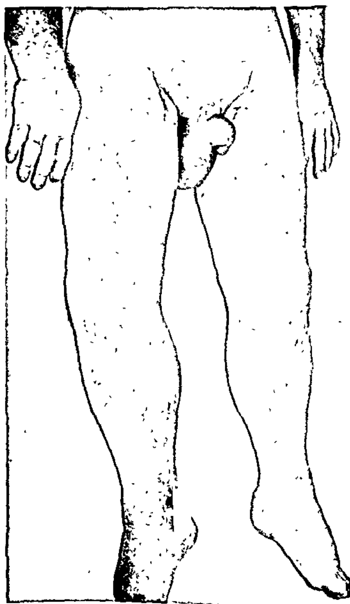

Fig. 15-28. Acute iliofemoral thrombophlebitis of both lower extremities and right axillary vein thrombosis.

and distended superficial veins, particularly on the dorsum of the foot However, in the presence of considerable swelling, this sign may be masked.

If the edema is limited to the foot and leg, the possibility exists that the level of thrombosis is in the popliteal vein. With extension of the swelling into the thigh, it can be assumed that the process is now located in the iliofemoral vein Edema of both lower extremities generally indicates that there has been either occlusion of the inferior vena cava or simultaneous involvement of both iliofemoral veins (Fig 15-28)

Complications. PHLEBOTHROMBOSIS The most serious complication of this condition is *pulmonary embolism.* Because the local phlebitic process in the limb is minimal and because the thrombus may propagate beyond the original site of formation, there is a tendency for portions of the clot to break off and be liberated into the blood stream Another complication is the extension of the thrombus into the main venous channel, producing complete occlusion In a sense, therefore, phlebothrombosis can at times be considered to be an early stage in the development of acute deep thrombophlebitis

ACUTE DEEP THROMBOPHLEBITIS Pulmonary embolism may occur in this condition, but it is seen much less often than in phlebothrombosis This is due to the fact that a phlebitic process is invariably present, so that the thrombus is usually firmly attached to the venous wall at its site of origin A much more frequent complication of acute deep thrombophlebitis is *the postphlebitic syndrome*, which follows prolonged venous stasis resulting from an inadequate collateral venous circulation. The signs which comprise this syndrome are pitting edema subsequently replaced by nonpitting edema, induration and brawniness of the skin, stasis dermatitis, pigmentation, secondary varicosities, and stasis ulcer (Fig 15-27) Subjectively the patient may complain of night cramps and a sense of heaviness and fatigue in the involved extremity Not infrequently the postphlebitic syndrome may be responsible for disabling sequelae which may *restrict* the patient's physical activity for months and even years

Diagnosis. SUPERFICIAL THROMBOPHLEBITIS No difficulty should be experienced in making the diagnosis of this condition. The presence of the local signs and symptoms in the leg and the absence of any systemic response are generally sufficient evidence to lead to the proper conclusion regarding the entity.

PHLEBOTHROMBOSIS. This condition is very difficult to diagnose because of the paucity of localized findings in the extremity. Unfortunately, in most instances its presence is only recognized when a pulmonary embolism occurs

ACUTE DEEP THROMBOPHLEBITIS Because of the obvious findings in the involved extremity, the diagnosis of this condition is readily made. The most important findings are the pain along the course of the involved vessel, the marked swelling of the limb, the prominence of and increased pressure in the superficial veins, and the systemic responses, such as fever of 100 to 101°F, malaise, and loss of appetite

Prognosis. SUPERFICIAL THROMBOPHLEBITIS. This condition is a relatively benign disorder with very few sequelae. Rarely, pulmonary embolism is associated with it Because the vessels involved are part of the superficial venous system, no interference with venous outflow occurs Therefore, sequelae dependent upon venous stasis do not appear If the thrombosis of the superficial veins is secondary to some systemic disorder, then, of course, the prognosis will depend upon the seriousness of the underlying difficulty.

PHLEBOTHROMBOSIS. The local changes in the extremity will in no way affect the efficiency of venous outflow and hence produce no disabling sequelae. However, the appearance of pulmonary embolism will markedly alter the prognosis of this disorder (Fig 15-29)

ACUTE DEEP THROMBOPHLEBITIS If the patient with this condition receives *anticoagulants early* in the disorder and if he is placed on complete *bed rest* with the involved limb *elevated*, there is a good possibility that his subsequent course will be associated with minimal difficulties Physical activity, particularly in the upright and sitting positions, will have to be limited somewhat in order to prevent swelling, but otherwise the patient should be able to lead a normal life Conversely, if the condition is treated incorrectly or if massive thrombosis has occurred, the patient may be left with a very inefficient

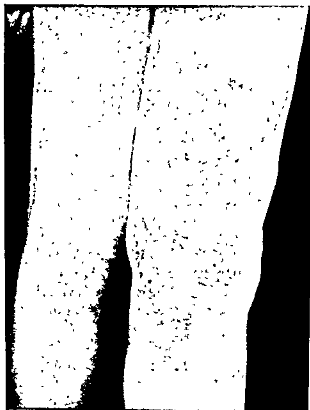

Fig. 15-29. Thrombophlebitis of numerous superficial veins on posterior surface of left thigh and leg (benign superficial thrombophlebitis). (*From Abramson Diagnosis and Treatment of Peripheral Vascular Disorders. Hoeber, 1956.*)

local venous system, which will limit his physical activity for many months or even years. With the appearance of the postphlebitic syndrome, the clinical picture becomes aggravated.

Treatment. SUPERFICIAL THROMBOPHLEBITIS Generally this condition does not require bed rest unless the thrombosed veins are so located that they are stretched with walking and, as a result, pain is caused The usual therapeutic approach is the application of an *elastic bandage* from the foot to above the highest level of thrombosis and instruction to the patient to become ambulatory If the thrombus continues to propagate and appears to be ascending the greater saphenous vein in the vicinity of the fossa ovalis, it is advisable to place the patient on *bed rest, elevate the foot of the bed* and even, at times, administer *anticoagulants*, e g , a combination of heparin and Dicumarol. *Ligation* of the involved vein above the level of thrombosis may at times also be necessary

PHLEBOTHROMBOSIS. In this condition, if the diagnosis is made early enough, *ligation* of the femoral vein below the point of entrance of the deep femoral vein may be performed, provided the exact location of the thrombotic process can be determined. However, it must be pointed out that this approach does *not* invariably prevent pulmonary embolism since, in about 10 per cent of cases, there are venous communications between the femoral vein and the deep femoral vein below the level at which the former is ligated (Edwards and Robuck). As a consequence, emboli arising in the venous plexuses of the calf may still be able to pass through the femoral vein into its communication with the deep femoral vein and then follow the latter into the systemic circulation A better approach to therapy involves the administration of a rapid-acting anticoagulant like *heparin*, together with *Dicumarol*, in order to prevent further propagation of the thrombus into the deep venous system, thus minimizing the probability of liberation of clots into the systemic circulation.

ACUTE DEEP THROMBOPHLEBITIS. In this condition, the patient should be at complete *bed rest*, with the *lower extremities elevated* so as to facilitate venous outflow. The *anticoagulants* should be given at once in order to decrease the tendency toward propagation of the thrombus into the collateral venous channels If there are signs of vasospasm, *wet heat* should be applied for periods of 3 hr, at 1-hr intervals, during the course of the day. The use of *sympathetic blocking agents* is also indicated The patient should remain on this regimen until all edema has disappeared and pain is no longer experienced along the course of the involved vein. Then he is allowed to be out of bed, but only while wearing an elastic stocking fitted for the limb. If, with the onset of the ambulation program, swelling reappears despite the use of compression, the patient should be put back to bed again. Anticoagulants are continued until full ambulation is reached. The *elastic stocking* should be worn until, by trial and error, it is found that compression is no longer necessary to prevent the appearance of swelling and that the patient is comfortable without its use.

Graphic data in diseases of the aorta and in the peripheral vessels

ALDO A. LUISADA AND EUGENIO JONA

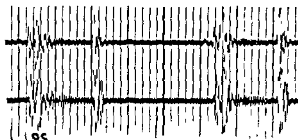
DISEASES OF THE AORTA

Phonocardiogram The phonocardiogram may reveal the following data.

1. An *opening click (or snap) of the aortic valve (ejection sound of aortic valve)*. This is a high and loud group of vibrations which precedes the rise of the carotid pulse by from 0 01 to 0 02 sec. It coincides with the opening of the aortic valve (Fig 15-30A). This phenomenon, described by Lian, and studied by Leatham and several others, causes an apparent splitting of the 1st sound It is due to lesions of the semilunar valves This click, *which is a* part of the 1st sound complex, is larger than the other group of vibrations occurring at the time of AV-valve closure The best frequency range for recording this click is in the 240 to 480-cps band, but there are components of even higher frequency, reaching up to 600 to 1,000 cps The best area for recording this click is the 3d *left* interspace (anatomical projection of the aortic valve), the next best is the *2d right* interspace.

2 A *triple rhythm*, due to addition of a loud systolic vibration (so-called *systolic gallop*). the 1st sound complex is followed by two or more low-pitched, high vibrations, which are simultaneous with the systolic expansion of the aorta (peak of the carotid wave). This rhythm is well recorded at the suprasternal notch (Luisada, 1938, Fig 15-30B).

3. The 2d sound consists of three to four large vibrations and may be prolonged by two or three smaller vibrations equivalent to a *short diastolic murmur*.



4 A *systolic murmur* is frequently present, its vibrations have the aspect of either a short, early systolic murmur, or of a diamond-shaped murmur. It is recorded best over the 2d or 3d *right interspaces*, but may be loudest at the left of the sternum

According to Aravanis and Luisada, an *early diamond is recorded* if there is a "relative stenosis" due to dilatation of the aorta. In "*obstructive stenosis*," on the other hand, the peak of the diamond is *late* (*late diamond*). An exception seems to occur in children, in whom even obstructive stenosis may have an "early diamond" shape (Nadas) possibly connected with the infundibular type of lesion.

Low-frequency Tracing. The apex cardiogram is of normal aspect or reveals a rapid, high pulsation. There is no slow, staggered rise as in aortic stenosis

Pulse and Pressure Tracings. Pulse tracings reveal a steep rise, a *sharp peak*, and a quick descent. These changes may be due to either aortic insufficiency or increased rigidity of the aortic wall. There is no anacrotic *depression* as in aortic stenosis. The pulse and pressure tracings of the lower extremities frequently reveal an increased pressure. The study of the pulse is particularly significant if the recording is made at the suprasternal notch (Aravanis and Luisada, Fig 15-31).

Atherosclerosis of the aortic arch may cause a smaller pulse and a lower blood pressure in

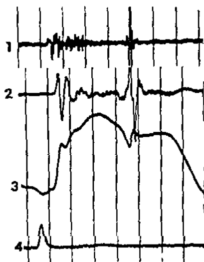


Fig. 15-30. A. Opening click (or ejection sound) (oc) in a patient with atherosclerosis of the aorta and initial calcific aortic stenosis. *Upper*, stethoscopic tracing, *lower*, filter tracing 120 to 240 cps; both over 2d right interspace. B. Low-frequency sound which accompanies the expansion of the aorta in a patient with a dilated atherosclerotic aorta. (1) Medium-high-frequency (120 to 240 cps) phonocardiogram at suprasternal notch showing an opening click and a short systolic murmur (2) Medium-low-frequency (40 to 120 cps) phonocardiogram at same area showing the low-frequency vibration. (3) Pulse tracing at same area (4) ECG

the arms (narrowing of the subclavian arteries). The resulting picture is the reverse of that in coarctation, and may reach its maximum in *Takayasu's syndrome*, or *pulseless disease*, where no graphic tracings are possible on the upper extremities.

Electrokymogram. Both the border tracings and the densograms of the ascending aorta and the aortic arch reveal pulsations of normal or increased magnitude. The pulses have a steep rise, a sharp peak, and a rapid descent. There is no anacrotism in the ascending limb. These data, like those of the pulse tracings, are useful for differential diagnosis in distinguishing other disorders from aortic stenosis.

Atherosclerosis of the Abdominal Aorta

Pulse Tracing; Phonoarteriogram. The tracing of the pulse of the femoral arteries has great amplitude. Its pattern consists of a sharp rise and a rapid drop.

A sound tracing over the 2d right interspace and simultaneously made femoral pulse tracing (or simultaneous pulse tracings of the suprasternal notch and the femoral arteries) reveal *an increased speed of the pulse* in the descending aorta. The femoral pulse normally is simultaneous with the brachial; in atherosclerotic patients, it may precede the brachial pulse.

A systolic murmur is frequently recorded over the abdominal aorta. In patients with an *aneurysm of the abdominal aorta,* the data are similar to those already described in syphilitic aneurysms (Part 9, Chap. 3).

CONCLUSIONS

Graphic data of diagnostic value are (1) a diamond-shaped aortic systolic murmur (phonocardiogram); (2) a large pulse with rapid rise and rapid fall (suprasternal tracing, aortic EKy); and (3) an apex cardiogram with rapid, high pulsation.

These data, together with the electrocardiogram (moderate or absent left ventricular hypertrophy, no bradycardia) are sufficient to exclude aortic stenosis, which might cause a similar systolic murmur.

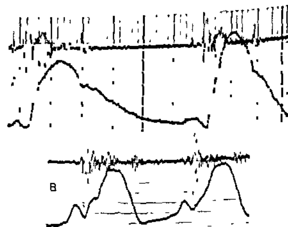

Fig. 15-31. A. Early diamond-shaped systolic murmur, normal aortic pulse (nonobstructive aortic stenosis, atherosclerosis of the aorta). B. Late diamond-shaped systolic murmur; slow rise and anacrotic depression of aortic pulse (obstructive aortic stenosis).

Study of the aortogram will help to confirm the diagnosis of atherosclerosis of the abdominal aorta.

GRAPHIC TRACINGS IN PERIPHERAL VASCULAR DISEASES

These tracings reveal the level of pressure in the various arteries, the amplitude of their pulsations, and the configuration of the pulses.

The most varied findings can be obtained In certain cases, *no pulse tracing* (and no indirect pressure tracing) can be obtained over certain arteries This is usually due to occlusion of the vessels However, *extreme narrowing of an artery* may still allow a thin, continuous flow of blood which cannot be appreciated from these tracings because of the absence of pulsation. A similar phenomenon may be observed in coarctation of the aorta (lower extremities only), as well as in aortic stenosis, shock, or congestive heart failure (all arteries) In cases of embolism, *absence of pulsations* below a given point is suggestive of arterial occlusion.

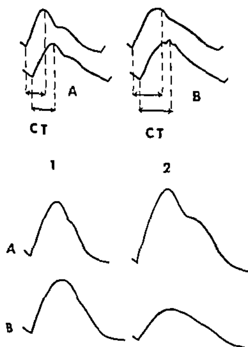

Fig 15-32. Upper Radial and digital pulses A, normal, B, peripheral arteriosclerosis, CT, crest time. Lower Changes in the arterial pulse of the lower extremities (1) before and (2) after exertion A, normal, increased amplitude, B, arteriosclerosis obliterans, decreased amplitude.

Fig 15-33. Phonoarteriogram and pulse tracing of a traumatic arteriovenous fistula at the groin Continuous murmur with systolic increase.

Senile arteriosclerosis is accompanied by changes in the configuration of both radial and digital pulses. In patients with this disease, *crest time* is markedly increased in both radial and digital tracings (Fig. 15-32, upper part). Younger persons with initial arteriosclerosis may also reveal an increase of the crest time of the digital pulse. It has been also noted that, in arteriosclerosis, the dicrotic waves decrease sharply and may disappear in the tracings of the fingers and toes.

Pulse and pressure tracings can be recorded before and after exertion Patients with organic arterial disease, with or without intermittent claudication, present an inverse reaction with decrease of blood pressure and smaller pulses in the lower extremities (Fig. 15-32, lower part).

In *arteriovenous fistula*, a normal (or high) systolic and a low diastolic pressure are observed. Pulse pressure is markedly increased; the pulse wave has an increased velocity. The predicrotic notch may be at a low level The arterial pulse may be weak and even disappear below the fistula.

Phonocardiogram. A sound tracing recorded *over the abdominal aorta* frequently reveals a systolic murmur in peripheral vascular diseases This murmur is probably due to the association of atherosclerosis of the abdominal aorta with obstruction of flow in the iliac or femoral arteries

In *arteriovenous fistula*, sound tracings reveal a continuous *murmur* with vibrations of both high and low pitch. The vibrations are larger during the expansion of the artery, smaller during its collapse (Fig. 15-33). The two phases coincide with ventricular systole

and diastole if the fistula is near the heart; they are delayed beyond these phases in more peripheral vessels.

The sound tracing has been used in differential diagnosis to exclude an arterial aneurysm compressing the veins. Such an aneurysm usually presents no audible diastolic murmur. However, the sound tracing may reveal minute diastolic vibrations, especially if there is aortic regurgitation Whenever the fistula is within the chest (aorta to superior vena cava), the murmurs increase during inspiration.

Surgical treatment of peripheral vascular diseases

Surgery of Venous Disorders

Surgery of Occlusive Arterial Diseases

R. B. LYNN

SURGERY OF VENOUS DISORDERS

Just as in occlusive arterial diseases, the surgery of venous disorders is virtually confined to affections of the veins of the lower extremities The conditions amenable to some form of surgical intervention are varicose veins, early deep-venous thrombosis, and the post-thrombophlebitic syndrome These diseases may complicate pregnancy or be associated with systemic disorders such as cardiac failure, atherosclerosis, diabetes, and obesity If this is the case, then the management of the associated condition may take precedence over the venous disorder, or its control may be necessary to ensure successful surgery. Thus, surgical and medical measures must be combined to ensure the patient the best results.

VARICOSE VEINS

Primary varicose veins and secondary or "compensatory" varicose veins, which provide additional embarrassment to the venous return in the postphlebitic limb, tend to progress if not treated The complications of untreated varices are varicose eczema or dermatitis, ulceration, hemorrhage, thrombophlebitis and, rarely, malignant degeneration in a varicose ulcer Most patients, however, first appear not with a complication but with vague complaints of aches, tiredness, and swelling, and their chief reason for seeking treatment is that the veins are unsightly. If conservative management of varicose veins, primarily by elastic support, is put aside, then the surgical measures available are sclerosant therapy and operative extirpation.

Sclerosant Therapy. The local injection of a chemical irritant into varicose veins is over 100 years old. The success of the method depends upon the careful selection of patients and the use of a substance which severely damages the intima of the vein and so produces obliteration of the lumen by formation of an organized thrombus. The best application of sclerosant therapy is in the treatment of localized varices which recur or remain after an adequate high ligation and stripping operation. Localized varices of the "vanity" type, and those associated with competent valves in the saphenous and communicating veins, complete the indications for injection treatment. Contraindications are previous deep thrombosis, severe occlusive arterial disease, and debilitating diseases, i e, in cardiac patients, where extensive thrombosis may ensue because of the associated circulatory stagnation. Injections into asthmatic patients must be administered with great care, as fatal allergic reactions have been reported

Although more than 20 substances have been recommended, the author uses only 0 5 to 2 0 ml of 5 per cent monoethanolamine oleate This soapy substance is a nontoxic, effective endothelial irri-

tant in the above dosage. The only equipment needed is a 2.0-ml syringe, a 1½-in. No 20 short-bevel needle, and sterile dressings. A tourniquet is not necessary. The vein is marked and the skin cleansed with tincture of iodine while the patient sits dangling the leg. The physician uses the "empty vein" technique, once the vein has been entered, the patient lies down and, after the position of the needle point has been rechecked by aspiration, 0.5 to 2.0 ml of the chemical is slowly injected. Emptying the vein ensures maximum local concentration and prolonged contact with the intima. After patient has been lying still for 10 min, a pressure pad is applied over the injection site, and full ambulation is resumed.

The incidence of pulmonary embolism after sclerosant therapy is about 1 in 15,000 cases but increases to 1 in 3,000 cases if prolonged rest is advised, since this leads to excessive thrombosis and spread to the deep venous system. This fact, too, emphasizes the danger of sclerosant injections when incompetent communicating veins are present. If repeated injections are needed they are administered at fortnightly intervals

Complications after injections should be rare if small volumes of irritant are used and the patients are carefully selected. Extensive thrombosis may occur, with spread to the deep veins, and, rarely, pulmonary embolism. Sloughing of the skin and an injection ulcer may follow extravasation or inadvertent injection of the chemical into the perivenous tissues These two complications are avoided by careful injection and the immediate cessation of injection if the patient complains of local pain or cramp in the calf of the leg. Suppurative phlebitis and local infection are rare. Recurrence of varices after injection is common, and when the recurrence is rapid a missed incompetent communicating vein, better treated surgically, must be suspected.

Surgical Measures. When the saphenofemoral valve is incompetent, with or without incompetent communicating veins, operative treatment is necessary for cure The operation of choice is high, "flush" saphenous ligation combined with stripping of the long saphenous vein, or short saphenous vein or both, from the ankle to the groin. Stripping of varicose veins is now 50 years old and has grown and declined in favor since it was introduced by Mayo. The indications for high saphenous ligation and stripping are (1) definite varices, (2) a history or presence of a complication, e.g., stasis ulceration or dermatitis; (3) the presence of combined deep and superficial insufficiency when it is proved that the superficial varices are adding to the venous stagnation in the limb; and (4) the presence of gross varices, in which case the process is prophylactic against complications. Contraindications include (1) pregnancy; (2) severe cardiovascular or renal disease; (3) severe occlusive peripheral vascular disease, (4) recent acute deep or superficial thrombophlebitis; (5) uncontrolled or infected stasis ulcers, and (6) uncontrolled metabolic disorders, e.g., diabetes, obesity.

Operative Techniques. If high saphenous ligation alone is to be performed, local anesthesia is preferable but, when stripping is desirable as well, as it is in most patients, the operation is performed under light general anesthesia. The supine patient is placed in a 10° Trendelenburg position to prevent venous stagnation; then the affected leg is allowed to externally rotate. The patient's previously shaved groin is carefully cleansed with soap and water or Cetavlon and then painted with tincture of iodine; the vulva or scrotum is avoided. A 5-cm vertical incision is made, this is centered 1.5 cm below and 2.5 cm lateral to the pubic tubercle and just medial to the femoral artery, which must be palpated. The vertical incision follows one of the first principles of vascular surgery, i.e., that the incisions for a vessel should be in the line of the vessel, this affords better exposure especially in the obese patient, prevents unnecessary mobilization of flaps which leads to hematoma formation and infection; and avoids division of inguinal lymphatics, thus preventing postoperative lymphorrhea and exacerbation of edema, which is especially important in the postphlebitic limb

The incision is deepened to expose the fossa ovalis, a selfretaining retractor is inserted, and, by means of blunt dissection, the termination of the saphenous vein and its tributaries are visualized. These branches are subject to wide variation and the surgeon is advised to rely upon an adequate exposure and complete dissection of the region, rather than upon classical anatomical descriptions, so that no tributary will be missed. Each branch (usually six in all) is carefully exposed, doubly ligated, and divided. After all the branches have been treated the saphenous vein is divided, at the distal end of the incision, and lifted upward so that the saphenofemoral junction can be clearly

visualized Clamps are never placed on the vein in this region The vein is now ligated flush with the femoral vein by means of No. 0 braided silk, and as insurance, a transfixion suture is placed 0.5 cm distal to it. The distal end of the vein is triangulated, and a malleable intraluminal stripper passed downward to the ankle, here a 2-cm incision is made, again vertical to avoid damaging the saphenous nerve, just in front of the medial malleolus. The termination of the long saphenous vein is located there, in the groove between the anterior border of the malleolus and the tibialis anticus tendon. The vein is tied distally with No. 00 plain catgut. The proximal end of the vein is doubly tied to the stripper with a 3-ft piece of No. 2 silk and then avulsed with a slow, steady pull If the stripper pulls off the vein, or if the vein inverts or breaks off, it can be retrieved and removed without additional incisions by means of the long silk thread. Often it is easier to pass the stripper upward from the ankle to the groin, and when this is done additional incisions are often necessary either to control large "blowouts" or when the veins are excessively tortuous As the vein is removed, pressure is exerted over the course of the stripped vein, and the leg is elevated to minimize hematoma formation. The incisions are closed in layers and a toe-to-groin elastic bandage applied. The patient is ambulatory that evening and leaves the hospital in 3 to 5 days

The short saphenous vein is varicose alone or together with the long saphenous vein in about 10 per cent of patients The short saphenous vein is visualized where it plunges into the popliteal fossa through a 5-cm transverse incision in the superior crease over the fossa It is seldom necessary to follow the vein to its junction with the popliteal vein since it rarely has branches entering it deep to the fascia of the fossa The short saphenous vein is doubly ligated proximally and then may be simply ligated distally after resection of a segment, or a stripper may be passed downward and picked up through a vertical incision just in front of the tendoachillis, 5 cm above the lateral malleolus The vein may then be stripped out, after this the incisions are closed and a pressure bandage is applied

The surgery of varicose veins is a major procedure and should only be performed by well trained, interested surgeons in a well-equipped operating room. Hemorrhage from torn tributaries or a torn femoral vein is the commonest complication and is best controlled by packing followed by enlargement of the incision to obtain proximal and distal control of the torn vessel, which can then be repaired. Blind clamping can cause further damage and must never be employed. Hematoma formation and infection are uncommon unless the operation is performed in the presence of an uncontrolled ulcer. The femoral artery has been torn, ligated, transected, and even injected. Deep venous thrombosis and pulmonary embolism (0 5 per cent of patients) may occur, but is now rare since injections are no longer combined with the surgical procedure. Some swelling of the ankle and lower leg may follow stripping but this is easily controlled by the wearing of elastic bandages or stockings for a few weeks and must not be allowed to interfere with the patient's activities. Occasionally, the saphenous nerve is damaged and the patient complains of paresthesia or even anesthesia over the inner side of the foot and ankle. This is usually temporary Recurrences are rare indeed and may be dealt with by postoperative injections in most patients, although occasionally the additional ligation of a "blowout" may be necessary High saphenous ligation and stripping gives an initial cure rate of over 90 per cent and is the procedure of choice in all superficial varices of the legs.

THROMBOSIS AND EMBOLISM

There is little place for surgery in the management of *deep-venous thrombosis* Some years ago, *prophylactic ligation of the superficial femoral veins* was advocated to prevent subsequent thrombosis and pulmonary embolism It soon became obvious that prophylactic proximal ligation not only did not reduce the number of fatal emboli but was also followed by chronic edema, ulceration, and all the features of a postphlebitic limb. Prophylactic *deep-vein ligation* is rarely, if ever, indicated

Proximal vein ligation has been advocated in established thrombosis, particularly when pulmonary embolism has occurred. Others still advocate it as a means to prevent *pulmonary embolism* after thrombosis has developed There is no real evidence, however, that such ligation is followed by a lower incidence of pulmonary embolism than would be expected

if the patient received good anticoagulant therapy. Usually, the femoral vein is explored through a vertical incision, similar to that used for high saphenous ligation, and the superficial femoral vein is exposed, then tapes are placed around it and its wall incised. Loose clot, if present, is sucked out, and then the vein is ligated distad to the profunda vein. Repair of the vein wall without ligation has been advocated when the operator feels sure he has removed all of the clot. If the common femoral vein is ligated, crippling edema is frequent. The criticisms of this procedure are that (1) it does not prevent emboli from arising proximally; (2) it cannot always be determined from which side the embolus came; and (3) not infrequently incision of the vein shows it to be filled with adherent clot so that it is obvious that a much more proximal ligation is necessary if the dubious principle of the procedure is to be justified. The only logical procedure to prevent all embolism is *inferior vena caval ligation*, and this crippling procedure is not to be lightly advised (Shea) If it is necessary, the approach is the same as that for a right lumbar sympathectomy The only indications for proximal deep vein or inferior vena caval ligation are (1) repeated pulmonary emboli not controllable by any other means, (2) nonavailability of adequate supervision of anticoagulant therapy, or (3) contraindication of anticoagulant therapy by the coexistence of other diseases or states, e g., hemorrhage from the gastrointestinal tract, some blood dyscrasias, jaundice, or severe renal or hepatic disease

Rarely, the *long saphenous vein is ligated* when superficial thrombophlebitis, which complicates varices, progressively ascends the thigh in spite of therapy. Fatal *pulmonary embolism* has occurred under such circumstances, and high saphenous ligation should be advised for progressively ascending superficial thrombophlebitis and performed under local anesthesia by the technique described above.

THE POSTTHROMBOPHLEBITIC SYNDROME

One of the consequences of a deep venous thrombosis is later recanalization of the formerly thrombosed vein; and with recanalization there is destruction of the venous valves. When this happens the usual reduction of pressure which occurs when the patient walks does not occur, and unremitting elevation of venous pressure develops in the limbs This leads to venous and capillary stagnation, which ultimately goes on to orthostatic edema, pain, pigmentation, dermatitis, and ulceration of the leg, which may or may not exhibit compensatory varicose veins. The original deep-venous thrombosis may have occurred so many years previously as to have been forgotten. Indeed, proof of a previous deep thrombosis is often completely lacking. When the postphlebitic syndrome is fully established, it may be treated conservatively or by a variety of surgical measures.

Nonsurgical Treatment. At least 90 per cent of postphlebitic limbs can be maintained in a good state of nutrition and their ulcers kept healed by means of a conscientous conservative regimen. The only part of any conservative treatment that is of the slightest importance is properly applied *elastic compression* This has been recognized for about 200 years, and still remains the most important part of any surgical treatment as well, although it is often not credited by various authors championing their favorite operation.

Elastic compression is best maintained by a strong, one-way-stretch elastic bandage applied before the patient gets out of bed in the morning and worn all day The bandage may have to be removed at intervals for readjustment or for dressing the ulcer Modern elastic stockings are not adequate to maintain firm elastic support. Unna's paste boots still have a place in treating the elderly, the debilitated, or those who cannot or will not use elastic bandages When it is available, physical therapy in the form of the Bisgaard routine may be added to the treatment A variety of nostrums has been advocated for healing these ulcers. The only necessary feature of such medicaments is that they shall do no harm, as none will heal an ulcer without elastic support. Modifications of Luke's "new way of life" are a necessary adjunct to the management of the patient.

Surgical Treatment. The surgical measures advocated for the relief of the postphlebitic syndrome are (1) *ligation* and *stripping* of compensatory superficial varices; (2) radical excision of the ulcer and associated varices, with or without skin grafting; (3) deep vein ligation alone or in combination with pro-

cedure (1) or (2) or both; and (4) lumbar sympathectomy.

Compensatory varicose veins are best eradicated by high saphenous ligation and stripping as described above This is done only when (1) the patient's general condition warrants it, (2) the ulcer (if present) is clean and controlled by elastic compression; and (3) it has been shown by the walking test that the deep veins are not obstructed Venography may be of value here This is the most frequently performed surgical procedure for the postphlebitic limb, and once the venous-lymphatic stasis has been improved by superficial vein surgery elastic compression will maintain the improvement.

Radical surgery is seldom necessary in the postphlebitic limb as even the worst-looking ulcer and the most scarred and indurated leg will heal with patient application of conservative measures. In a small number, probably 2 to 3 per cent of patients, the ulcer may seem indolent, malignancy may be suspected, or the patient, surgeon, or both become impatient, and radical surgery is advised. There is, however, no surgical procedure which alone will maintain healing in the surgically corrected leg without permanent postoperative elastic compression The radical operations employ long incisions to include the ulcer at the ankle and so excise all the dense scar tissue in and around the ulcer, but primarily they excise completely the incompetent communicating veins invariably present in the ankle region of the postphlebitic leg Once this excision is complete, it may be necessary to cover the excised area with a split-thickness skin graft Permanent postoperative elastic support to the limbs is necessary to prevent recurrence of ulceration, in spite of radical surgery

Deep vein ligation in the plostphlebitic syndrome was first advocated by Homans (1937) and later championed by Bauer (1955) and Linton (1953b). It has been clearly shown that ligation of the superficial femoral vein (Homans, Linton) or the popliteal vein (Bauer) actually increases venous stasis in the limb and the author cannot recommend these procedures. The author has tried and discarded these irrational methods because they neither influence ulceration nor improve edema, indeed they often make it worse, and only occasionally do they relieve pain in the limbs. This uncommon "bursting" type of pain can be equally well controlled by adequate elastic support, without the disadvantages of interrupting an important blood vessel It is unfortunate that venography ever showed retrograde flow in postphlebitic limbs, as reflux occurs almost as often in the normal limb. If retrograde venography had not been so often misinterpreted, many ligated veins would still be performing a useful (albeit impaired) function and carrying blood back to the heart.

Sympathectomy has an even smaller place in the management of the postphlebitic limb than has radical surgery It will never heal and maintain healing in an ulcer without ancillary measures *Lumbar sympathectomy* should be restricted to the occasional postphlebitic limb which has a superimposed occlusive or vasospastic vascular disease, e g, atherosclerosis, hyperhidrosis, or chilblains In patients with such "combined" ulcers, lumbar sympathectomy will enhance nutrition and abolish sweating, as well as the often troublesome dermatophytosis which develops on the macerated hyperhidrotic foot. Even so, prolonged elastic support is necessary to prevent recurrence Since the main problem in the postphlebitic limb is venous stagnation, and since lumbar sympathectomy will only increase arterial inflow and so place an additional burden on lymphatic and venous return, the procedure is generally contraindicated in chronic deep-venous incompetence.

SURGERY OF OCCLUSIVE ARTERIAL DISEASES

It should be emphasized that far more patients with occlusive disease of the peripheral arteries are treated by conservative than by surgical means and that many surgical procedures will fail unless combined with the so-called "conservative" measures Thus, protection of the ischemic limb from trauma, avoidance of undue heat or cold, weight reduction, correction of anemia and diabetes, and the absolute cessation of smoking, are some factors which, if controlled, will ensure that the moderate but important part that surgery has to play is given the best chance of success

The main objectives of surgery in occlusive

arterial diseases are (1) *improvement of the nutrition* of the ischemic limb by increasing its blood supply; (2) *the relief of intermittent claudication;* and (3) *amputation* of gangrenous tissue when all other forms of treatment fail. There are three major occlusive diseases to which these objectives are applied: atherosclerosis, thromboangiitis obliterans, and Raynaud's disease. By far the greatest number of candidates for surgery suffer from atherosclerosis (with or without associated diabetes), 90 per cent in the author's experience.

Current interest is centered upon the technical aspects of the surgical measures available for relief of obliterative arterial disease and, because of this, there is a prevailing impression that the majority of patients are eligible only for one certain surgical procedure. Accordingly, the author has chosen to emphasize the selection of patients and the indications for the various procedures available to the surgeon. The intimate technical details of the surgical methods will not be stressed, as they are readily available in texts on surgical methods.

METHODS OF INCREASING PERIPHERAL BLOOD FLOW

The blood supply to an ischemic limb may be increased by direct or indirect surgery. *Indirect surgery,* in the form of lumbar or cervicodorsal sympathectomy, still remains the operation of choice in peripheral occlusive vascular disease (Smithwick, 1957). *Direct surgery,* in the form of arterial reconstruction, is the method of choice when more proximal major vessels are the seat of disease, e.g., aorta and iliac arteries. It must be appreciated that obliterative arterial diseases are generalized, and the whole patient must be considered, not just the limb Thus, complete investigation of the cardiovascular status of each patient must precede surgery because of the frequent association of peripheral vascular disease with coronary, cerebrovascular, and renal diseases There is little point in subjecting a patient to a major operation only to convert him into a cardiac cripple from precordial pain which was masked by the reduced exercise tolerance consequent to claudication

Sympathectomy. There is conflicting evidence on the importance of the sympathetic innervation of skeletal muscle in man It can be stated, however, that release of vasoconstrictor tone of muscle arteries by sympathectomy is of little importance and has little effect on the vessels of limbs with claudication Thus, sympathectomy must not be offered to the patient *solely* for the relief of intermittent claudication, as it will not relieve the pain arising from muscle activity except in the rare case of isolated high major vessel block (which is now best treated by direct surgery). *Lumbar and cervicodorsal sympathectomy are indicated when ischemia of the skin, with or without minor ulceration or gangrene, is present* Coldness, paresthesia, and rest pain are often dramatically relieved by sympathectomy. Similarly, in a properly selected patient, ischemic ulcers may heal and local gangrene may be restricted. Also, if cutaneous blood flow and nutrition are improved, a major amputation may be avoided. Age is no contraindication if other factors are favorable—the author has successfully relieved ischemic ulceration in an 86-year-old woman by performing lumbar sympathectomy.

Certain preoperative tests are necessary before any patient can be selected for sympathectomy. The use of sympathectomy in a "let's see what will happen" manner has unfortunately brought this most valuable procedure into disfavor in many centers. The results of sympathectomy in the treatment of occlusive vascular diseases of the limbs are dependent upon the care with which patients are selected for surgery. Before sympathectomy can be advocated, it is necessary to demonstrate a definite release of vasomotor tone by means of reflex heating, paravertebral or peripheral nerve block, or the intraarterial injection of a vasodilator drug. The degree of release of vasoconstrictor tone is measured by cutaneous temperature responses or, preferably, by plethysmography (Part 4, Chap 3). These methods are not infallible and more than one test always must be made. The degree of response is an index of the ability of the ischemic tissues to dilate in response to sympathetic denervation. In virtually all cases of obliterative vascular disease, delineation of the vessels by *arteriography* is advocated. This technique enables the surgeon to exclude the patient who might be suitable for arterial reconstruction and also to recheck release of vasoconstrictor tone when the patient is under anes-

thesia. If the patient is selected for sympathectomy, lumbar sympathectomy will be performed for occlusive arterial disease of the legs, cervicodorsal sympathectomy if the arms are involved

LUMBAR SYMPATHECTOMY. The lumbar sympathetic chains lie on the anterolateral aspects of the vertebral column along the medial edges of the psoas muscles The lumbar vessels usually lie behind the chains but, not uncommonly, on the right the veins in particular lie in front of the chain. The right chain and ganglia are overlapped by the inferior vena cava and the left chain lies just lateral to the aorta. Four lumbar ganglia are usual, five or more are uncommon, and in exceptional cases there may be only one or two. Asymmetry of the two sides is normal and the positions, sizes, and shapes of the ganglia are inconstant. They may be unequal in size and elongated or flattened in shape Removal of the second and third ganglia and the intervening portion of chain will denervate the leg below the knee but, if denervation of the leg to the groin is desired, the first ganglion must also be removed Because of the anatomical irregularities in the chains, it will be appreciated that such precise removals are impractical. Accordingly, *it is the author's practice to remove the entire lumbar sympathetic chain from the brim of the pelvis to (and including) the ganglion which lies under the crus of the diaphragm* This ganglion is most probably always the first lumbar ganglion and is constant in site and shape, in that it resembles a Scotch thistle because all its rami enter and leave it superiorly Sterility in the male from bilateral removal of both first lumbar ganglia is not invariable and, if a complete sympathectomy is desired, both first lumbar ganglia must be removed, otherwise the collateral vessels around the block will not be denervated

Technique. General anesthesia augmented by muscle relaxants is the anesthetic procedure of choice Spinal anesthesia should not be used because there is danger of hypotension and the concomitant ill effects of compensatory vasoconstriction in the unanesthetized upper half of the body including the coronary arteries With the patient slightly flexed and lying in a semioblique position on the opposite side, a 10-cm transverse incision is made This extends from the tip of the twelfth rib to the lateral border of the rectus muscle The incision is deepened to the external oblique muscle which is split along the line of its fibers The internal oblique and transversus muscles are similarly split along the lines of their fibers to expose the peritoneum Beginning at the posterior end of the incision, the peritoneum is reflected forwards and medially together with the ovarian or testicular vessels and the ureter. The psoas muscle with the genitofemoral nerve on its surface is thus exposed and the lumbar chain will be seen (sometimes, in fat subjects, more easily felt at first) at its medial edge under the inferior vena cava, on the right side and lateral to the aorta on the left. After these structures have been gently retracted medially, the chain is picked up with a blunt hook and all its communications are divided with scissors Special care must be taken to recognize the lumbar vessels which may occasionally lie in front of the chain, particularly on the right side; where this occurs the chain must be carefully drawn under them The chain is followed down to the brim of the pelvis and then up to the crus of the diaphragm, which is split to expose completely the first lumbar ganglion; this is recognized by the oblique entry of all its rami from above The chain is avulsed above the first ganglion If this procedure is followed, at least 10 cm of chain and ganglia will be routinely removed. The muscle layers are then loosely approximated with catgut and the skin closed with silk There is no need for drainage and, if the operation is performed under general anesthesia with relaxants, it should not take more than 10 min When there are signs of ischemia in the opposite limb, it is the author's practice to remove both lumbar chains at one operation. The muscle splitting incision is preferred to muscle cutting because of its simplicity, its anatomical soundness and, most important, its avoidance of all blood vessels It is rarely necessary to apply a hemostat during the operation.

Although this is the standard operation, it may, on rare occasions, be necessary to use the transperitoneal route, e.g, in a patient with aortic thrombosis not suitable for excision and grafting. The chains are approached through a midline abdominal incision to avoid all the collateral vessels which may be participating in the blood supply to the legs The right chain is found behind the peritoneum, below and to the left of the root of the mesentery and medial to the ureter. The left chain is revealed by reflecting the descending colon and splenic flexure medially. It is difficult and often impossible to remove the first lumbar ganglion when this approach is used.

The mortality rate for lumbar sympathectomy is negligible, and the operation can be tolerated by patients up to 86 years of age. The side effects are (1) *anhidrosis* of the denervated extremity, (2) variable *sterility* in the male if both first lumbar ganglia are removed, (3) compensatory *sweating* in the normally innervated half of the body—this is a problem only in warm climates, and (4) the *postsympathectomy syndrome.* The latter commences

arterial diseases are (1) *improvement of the nutrition* of the ischemic limb by increasing its blood supply; (2) *the relief of intermittent claudication;* and (3) *amputation* of gangrenous tissue when all other forms of treatment fail. There are three major occlusive diseases to which these objectives are applied: atherosclerosis, thromboangiitis obliterans, and Raynaud's disease. By far the greatest number of candidates for surgery suffer from atherosclerosis (with or without associated diabetes), 90 per cent in the author's experience.

Current interest is centered upon the technical aspects of the surgical measures available for relief of obliterative arterial disease and, because of this, there is a prevailing impression that the majority of patients are eligible only for one certain surgical procedure. Accordingly, the author has chosen to emphasize the selection of patients and the indications for the various procedures available to the surgeon. The intimate technical details of the surgical methods will not be stressed, as they are readily available in texts on surgical methods.

METHODS OF INCREASING PERIPHERAL BLOOD FLOW

The blood supply to an ischemic limb may be increased by direct or indirect surgery. *Indirect surgery,* in the form of lumbar or cervicodorsal sympathectomy, still remains the operation of choice in peripheral occlusive vascular disease (Smithwick, 1957) *Direct surgery,* in the form of arterial reconstruction, is the method of choice when more proximal major vessels are the seat of disease, e.g , aorta and iliac arteries. It must be appreciated that obliterative arterial diseases are generalized, and the whole patient must be considered, not just the limb. Thus, complete investigation of the cardiovascular status of each patient must precede surgery because of the frequent association of peripheral vascular disease with coronary, cerebrovascular, and renal diseases. There is little point in subjecting a patient to a major operation only to convert him into a cardiac cripple from precordial pain which was masked by the reduced exercise tolerance consequent to claudication.

Sympathectomy. There is conflicting evidence on the importance of the sympathetic innervation of skeletal muscle in man. It can be stated, however, that release of vasoconstrictor tone of muscle arteries by sympathectomy is of little importance and has little effect on the vessels of limbs with claudication. Thus, sympathectomy must not be offered to the patient *solely* for the relief of intermittent claudication, as it will not relieve the pain arising from muscle activity except in the rare case of isolated high major vessel block (which is now best treated by direct surgery). *Lumbar and cervicodorsal sympathectomy are indicated when ischemia of the skin, with or without minor ulceration or gangrene, is present.* Coldness, paresthesia, and rest pain are often dramatically relieved by sympathectomy. Similarly, in a properly selected patient, ischemic ulcers may heal and local gangrene may be restricted. Also, if cutaneous blood flow and nutrition are improved, a major amputation may be avoided. Age is no contraindication if other factors are favorable—the author has successfully relieved ischemic ulceration in an 86-year-old woman by performing lumbar sympathectomy.

Certain preoperative tests are necessary before any patient can be selected for sympathectomy. The use of sympathectomy in a "let's see what will happen" manner has unfortunately brought this most valuable procedure into disfavor in many centers. The results of sympathectomy in the treatment of occlusive vascular diseases of the limbs are dependent upon the care with which patients are selected for surgery. Before sympathectomy can be advocated, it is necessary to demonstrate a definite release of vasomotor tone by means of reflex heating, paravertebral or peripheral nerve block, or the intraarterial injection of a vasodilator drug The degree of release of vasoconstrictor tone is measured by cutaneous temperature responses or, preferably, by plethysmography (Part 4, Chap. 3). These methods are not infallible and more than one test always must be made. The degree of response is an index of the ability of the ischemic tissues to dilate in response to sympathetic denervation. In virtually all cases of obliterative vascular disease, delineation of the vessels by *arteriography* is advocated. This technique enables the surgeon to exclude the patient who might be suitable for arterial reconstruction and also to recheck release of vasoconstrictor tone when the patient is under anes-

thesia If the patient is selected for sympathectomy, lumbar sympathectomy will be performed for occlusive arterial disease of the legs, cervicodorsal sympathectomy if the arms are involved.

LUMBAR SYMPATHECTOMY. The lumbar sympathetic chains lie on the anterolateral aspects of the vertebral column along the medial edges of the psoas muscles The lumbar vessels usually lie behind the chains but, not uncommonly, on the right *the veins in particular lie in front* of the chain The right chain and ganglia are overlapped by the inferior vena cava and the left chain lies just lateral to the aorta Four lumbar ganglia are usual, five or more are uncommon, and in exceptional cases *there may be only one or two. Asymmetry* of the two sides is normal and the positions, sizes, and shapes of the ganglia are inconstant They may be unequal in size and elongated or flattened in shape Removal of the second and third ganglia and the intervening portion *of chain will denervate* the leg below the knee but, if denervation of the leg to the [illegible]
also [illegible]
lant [illegible]
such precise removals are impractical. *Accordingly, it is the author's practice to remove the entire lumbar sympathetic chain from the brim of the pelvis to (and including) the ganglion which lies under the crus of the diaphragm.* This ganglion is most probably always the first lumbar ganglion and is constant in site and shape, in that it resembles a *Scotch thistle* because all its rami enter and leave it superiorly. *Sterility in* the male from bilateral removal of both first lumbar ganglia *is not* invariable and, if a complete sympathectomy is desired, both first lumbar ganglia must be removed, otherwise the *collateral* vessels around the block will not be denervated

Technique General anesthesia augmented by muscle relaxants is the anesthetic procedure of choice Spinal [illegible]

[illegible] the coronary arteries. With the patient slightly flexed and lying *in* a semioblique position on the opposite side, a 10-cm *transverse* incision is made This extends from the tip of the twelfth rib to *the* lateral border of the rectus muscle. The incision is deepened *to* the external oblique muscle which is split along the line of its fibers. The internal oblique and transversus muscles are *similarly* split along the lines of their fibers to expose the peritoneum *Beginning* at the posterior end of the incision, the peritoneum *is reflected* forwards and medially together with the ovarian or testicular vessels and the ureter. The psoas muscle with the genitofemoral nerve on its surface is thus exposed and the lumbar chain will be seen (sometimes, in fat subjects, more easily felt at first) at its medial *edge* under the *inferior* vena cava, on the right side and lateral to the *aorta on the left.* After these structures have been gently retracted medially, the chain is picked up with a blunt hook and all its communications are divided with scissors. *Special* care must be taken to recognize the lumbar *vessels which may occasionally* lie in front of the chain, particularly on the right side; where this occurs the chain must be carefully drawn under them The chain is followed down to the brim of the pelvis and then up to the crus of the diaphragm, *which is split to expose completely* the first lumbar ganglion; this is recognized by the oblique entry of all its rami from above. The chain is avulsed above the first ganglion. If this procedure is followed, at least 10 cm of chain and ganglia will *be routinely removed.* The muscle layers are then loosely approximated *with catgut and the* skin closed with silk. There is no need for drainage and, if the operation is performed under general anesthesia with relaxants, it should not take more than 10 *min* When there are signs of ischemia in the opposite limb, it is the *author's practice* to remove both lumbar chains at one operation. The muscle splitting incision is preferred to muscle cutting because of its simplicity, its anatomical soundness and, *most* important, its avoidance of all blood vessels. It is *rarely necessary to* apply a hemostat during the operation

Although this is the standard operation, it may, *on rare* occasions, be necessary to use the transperitoneal route, *e g*, *in* a patient with aortic thrombosis not suitable for excision and grafting The chains are approached through a midline abdominal incision to avoid all the collateral vessels which *may* be participating in the blood supply to the legs. The right *chain is found* behind the peritoneum, below and to the left of *the root of* the mesentery and medial to the ureter The left chain *is* revealed by reflecting the descending colon and splenic flexure medially. It is difficult and often impossible to remove the *first* lumbar ganglion when this approach is used

The mortality rate *for* lumbar sympathectomy is negligible, and the operation can be tolerated by patients up to 86 *years* of age. The side effects are (1) *anhidrosis* of the de- [illegible]

[illegible] innervated half of the body—this is a problem only in warm climates; and (4) the *postsympathectomy syndrome.* The latter commences

Fig. 15-34 Horner's syndrome.

as a discomfiting, deep-seated, gnawing pain in the thigh, it is worse at night and is frequently accompanied by hyperesthesia of the overlying skin and quadriceps wasting. Although the exact source of this pain is not certain, it is probably due to degeneration of the white rami communicantes connecting with the first, second, and possibly the third lumbar spinal segments. The pain always disappears within three weeks to three months and is best controlled by analgesics. Physical therapy in the form of heat and quadriceps drill is sometimes helpful.

CERVICODORSAL SYMPATHECTOMY. Denervation of the upper extremity is less satisfactory than denervation of the leg and is always followed by some degree of return of vasoconstrictor tone, a complication which never follows lumbar sympathectomy. This is primarily due to the variability of sympathetic outflow to the upper extremity and the existence of intermediary ganglia. The preganglionic outflow in man is primarily from the second to seventh thoracic segments, inclusive. After ascending in the gangliated chain, the major relay is in the *stellate ganglion*. (In 80 per cent or more of subjects, the inferior cervical and first thoracic ganglia are fused to form the stellate ganglion.)

The stellate ganglion is creamy pink, 1.5 to 2.5 cm long, and irregular in shape, it derives its name from the radiation of branches from it. It lies anterior to the neck of the first rib and the eighth cervical transverse process, and medial to the superior intercostal artery and vein. The vertebral vessels lie close to its superior pole and the subclavian artery lies immediately anterior to it. The ganglion lies posterior to the apex of the lung which is often thickened by a musculoaponeurotic slip from the scalene muscles which forms Sibson's fascia. The stellate ganglion is connected to the second thoracic ganglion which lies on the neck of the second rib.

The second ganglion is the key ganglion, as its removal alone will lead to preganglionic denervation of the arm in nearly every patient (although more extensive sympathectomy is desirable). However, removal of the stellate ganglion is invariably followed by *Horner's syndrome* and this complication, particularly when unilateral, is unsightly (Fig. 15-34). The best procedure for complete denervation of the upper extremity is removal of the stellate, second, and third thoracic ganglia, but most surgeons and patients prefer to compromise and leave the stellate ganglion intact and so prevent (1) Horner's syndrome, (2) nasal obstruction from hyperemia of the nasal mucosa, (3) excessive dandruff due to the anhidrosis, and (4) occasional gustatory sweating. The advantages of a slightly longer period of freedom from return of vasomotor tone after a cervicodorsal sympathectomy which includes the stellate ganglion are outweighed by the disadvantages outlined above since some degree of return of vasomotor tone is invariable regardless of the operation. It is now recognized that there is no practical clinical advantage of pre- over postganglionic resection, so this problem will not be mentioned further.

Technique. The anterior operation is the simplest and least traumatizing and it has the advantage that bilateral sympathectomy can be safely accomplished in one operation. Axillary and posterior approaches are described but have no advantages over the anterior route and possess very real disadvantages.

Under general anesthesia, the patient is intubated in case the pleura is inadvertently opened and a small sandbag is placed between his scapulas, his head is turned to the opposite side, and his arm is pulled downward to open up the supraclavicular space. A 3-in. incision is made, beginning over the inner border of the clavicular head of the sternomastoid muscle 2 cm above the clavicle and running laterally. The platysma muscle is divided along the line of the incision. The external jugular vein, which is in the outer angle of the incision,

can be retracted The clavicular head of the sterno- ... from its insertion The ... tissue over- ... may be divided. By means of gauze dissection the scalenus muscle will be exposed with the phrenic nerve running downwards and medially across its surface The nerve is mobilized and retracted medially with a tape. The edges of the scalenus muscle are defined and the subclavian artery will be seen emerging from beneath its outer border The insertion of the muscle into the first rib is nibbled through while the artery is protected from behind by a right-angled clamp or malleable spatula. If the muscle substance is cut into, troublesome bleeding occurs Once the scalenus is completely divided, the first and second parts of the subclavian artery come into view. In cases of occlusive vascular disease, the operation should be continued by approaching the chain from below the subclavian artery, since no branch of the subclavian artery must be divided, it might be an important collateral The neck of the first rib is felt for, and the apical pleura can usually be elevated from the necks and adjacent shafts of the upper three ribs by finger dissection Occasionally, it is necessary to incise the apex of Sibson's fascia. The superior intercostal artery and vein must be avoided because, if they are torn, they can be the source of troublesome bleeding, this is best controlled by coagulation or packing It is convenient to depress the apex of the lung with a lighted retractor. The chain should now be readily felt and seen running downward and backward It is divided distal to the third thoracic ganglion and dissected upward, thus dividing all the rami to the third and second ganglia The cut end of the chain is then stitched to the cut end of the scalenus anticus muscle to delay regeneration If the stellate ganglion is to be removed, it is easily freed of all its divisions and the cervical chain is cut above it The stellate ganglion is, however, usually left intact Once the sympathectomy of choice has been completed, the incision is filled with saline solution and the anesthetist inflates the lung Thus, an inadvertent pneumothorax may be detected and evacuated The incision is closed in layers without drainage by approximating the clavicular head of the sternomastoid muscle, the platysma muscle, and the skin If surgery of both sides is to be performed, the patient's head is turned to the other side and the above procedure repeated

The mortality rate is negligible but the results of cervicodorsal sympathectomy are inferior to those of lumbar sympathectomy because of the degree and inevitability of return of vasomotor tone

Arterial Reconstruction. The best method of increasing the peripheral blood flow is to remove the offending obstruction and so permit unrestricted blood flow to the extremity. Two methods are available for this: (1) thromboendarterectomy, and (2) blood-vessel grafts (artery, vein, or fabric). Perusal of the current literature leaves one with the impression that most patients suffering from occlusive vascular disease are suitable candidates for restorative surgery. This is far from the truth, especially when the disease is in the legs, less than 15 per cent of the cases seen by surgeons can be accepted Even this figure is inflated because of prior selection before referral to the surgeon. The number of suitable patients is higher when the disease involves the aorta and iliac vessels but here, too, the success of the procedure depends upon the peripheral vessels being free from disease, which they seldom are. Thus, *arteriography* or *aortography* must precede any direct surgical attack on an obliterated artery. The most important points to be determined are the size, the patency, and the state of the distal vessel wall The best results will follow aortic and iliac occlusions Limited success will follow femoral artery surgery and it is only in an exceptional case that a good result follows direct surgery on more distal vessels. Patients with claudication alone should not be subjected to these procedures unless the pain is so severe that they cannot work. On the other hand, when rest pain or ... tomical feat ... is advised ... harm can follow an unsuccessful graft or disobliteration because the alternative is amputation of the limb Strict selection is the key to success in any direct surgery

THROMBOENDARTERECTOMY. This operation is possible in less than 1 per cent of patients with occlusive arterial diseases of the extremities. It is of no value in *Buerger's disease* because of the nature of the arterial disease in thromboangiitis obliterans, obliteration of small arteries is the rule and obstruction of a major artery uncommon. Arteriography is necessary, and a well-localized obstruction in a vessel free from calcification is essential for success (Fig 15-35). Originally long segments were obliterated, but initial success was followed by early thrombosis and recurrence of symptoms.

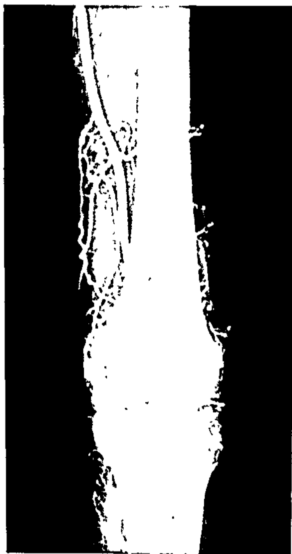

Fig. 15-35. Wasp-waist constriction of popliteal artery, free from atheroma and ideal for endarterectomy.

Better results are obtained in the iliac vessels, but here grafts are preferable except in the case of local obstructions (Fig 15-36).

Technique. The principle of thromboendarterectomy is to remove the obliterated segment through a plane of cleavage in the media Thus the atheromatous plaques and thrombus are removed along with the intima and media out to but not including the external elastic lamina The adventitia and the outer layer of the media remain as the vessel wall. Although the remaining artery wall is attenuated it is capable of withstanding the arterial blood pressure without aneurysm formation. Long-term anticoagulant therapy, for years if necessary, will ensure that recurrent thrombosis is rare.

The artery is exposed through a long skin incision overlying the thrombosed segment A longitudinal incision is made into the vessel wall after establishment of proximal and distal control of the patent portions of the vessel by means of bulldog clamps Careful blunt dissection with a MacDonald dissector will develop a plane of cleavage in the media. The thrombus can then be easily stripped up and down the vessel. Bleeding from collaterals is controlled by means of small bulldog clamps. Once the offending thrombus is removed, the intima of the proximal and distal portions of the vessel must be stitched to the vessel wall in order to prevent dissection and thrombosis. The vessel wall is carefully sutured with No 00000 arterial silk and the clamps are removed. Multiple short incisions may be made, rather than a single long one, and special strippers may be used to mobilize the thrombus, but when this is done there is an implication that too long a segment is being disobliterated The incision is closed without drainage and heparin is started 6 hours postoperatively. Long-term anticoagulant therapy is commenced the next day with a Dicumarol derivative and is continued for months or years to minimize recurrent thrombosis

BLOOD VESSEL GRAFTS. The materials available for arterial grafting are autogenous veins,

Fig. 15-36. Local obstruction in common iliac artery, ideal for endarterectomy.

heterologous arteries, various fabrics, and homologous arteries Arterial heterografts are the least satisfactory substitutes Autogenous veins are preferable to fabric prostheses in peripheral vessels, but vein grafts are not suitable in the aorta or iliac vessels because of possible aneurysm formation, thrombosis, and calcification Synthetic textiles (Orlon, Dacron, nylon, etc) work well in the aorta and the iliac arteries but commonly thrombose in arteries the size of the femoral and popliteal They should only be used, at present, in older patients, or when a homologous preserved artery is not available Thus, homologous freeze-dried arteries are preferable as grafts in all sites. The preparation and storage of these grafts in "banks" is *now routine. The best alternative in peripheral vessels is an autogenous vein, where the site will be supported by the patient's tissues, e g., superficial* femoral artery in Hunter's canal.

Technique of Vascular Anastomosis End-to-end anastomosis of the vessel and the graft is carried out by means of either an everting *mattress or* continuous over-and-over stitch of Nos 00000 *or* 0000 arterial silk or Mersalin The end-to-end technique is necessary in the repair of *major* arteries. *Recently*, the bypass technique has become more *popular*, since it (1) allows a larger anastomosis *to be made* (2) [illegible]

quir [illegible]

of e[illegible]

geon to choose a healthy part *of the vessel wall* for his suture line. The early *optimism, however,* is now receding and the *bypass is not considered to be any more successful, on a long-term basis, than the end-to-end procedure, and it has not widened the indications for direct surgery* In the bypass method, the end of the graft *is sutured* into the side of the artery above and below the obliterated *segment by* means *of* an everting mattress stitch with silk In atherosclerotic vessels, a continuous over-and-*over stitch* is preferable to the everting mattress stitch *and* the needle must always pass from the inside *of the* host artery outward This maintains *apposition* of the intima and media of the atherosclerotic *artery* and prevents lifting up of atheromatous plaques and dissection of the vessel wall

Where fabric is used, the usual arterial *anastomosis* is made but, before the clamps are permanently released, the graft should be allowed to fill with the patient's blood in order that the *interstices of the* textile may fill with fibrin and so excessive bleeding *will be* avoided. Preclotting of the tube using the recipient's blood *may also be* used, if care is taken to express all clot before the final anastomosis is made Fabric is more difficult to sew because it lacks elasticity. Fabric prostheses must also be precisely correct in their length or buckling and thrombosis are likely to occur. However, they do not interfere with blood flow distally and doubtless will be the graft material of the future, when an ideal fabric, biologically inert, strong, flexible, and clot-resistant is available *since* the fabric, as well as a *freeze-dried graft, is primarily a strut. When preserved artery grafts are* used, the elastic fibers remain, but show marked degeneration in later years and the questions of late aneurysm formation, early degeneration, and calcification of the grafts are not yet *completely settled.*

Relief of Intermittent Claudication. The most common complaint in occlusive vascular disease is *pain in the calf on walking (intermittent claudication).* This pain may occur elsewhere, i e , in the buttock, thigh, and foot. In high arterial blocks, claudication may be improved by *sympathectomy but this is not* usual. Relief *of claudication* is usual after a *successful* arterial reconstruction, but relief of pain, alone, should not be the object of direct surgery unless the pain is crippling. There *are still* occasional patients who have good peripheral nutrition and in whom sympathectomy has not relieved intermittent claudication. For them, disabling claudication *can be relieved* or improved by inactivation of the muscles of the *painful calf,* almost always the gastrocnemius. *The* procedures—gastrocnemius *neurectomy* and tendo achillis *tenotomy*—are purely palliative and have no effect on the *peripheral* circulation or nutrition.

NEURECTOMY Gastrocnemius neurectomy is performed through a *short vertical* incision beginning at the crease behind the knee joint over the popliteal fossa and *extending* distally 10 cm The fascia is split, the *short* saphenous vein is retracted, and the muscular *branches to* the two heads of the gastrocnemius *identified and* confirmed by stimulation An inch *or so of each* nerve is resected and the incision closed in layers. There is no need to denervate *the* soleus as *it rarely* causes claudication. The foot and calf of the *leg* are supported postoperatively by an elastic bandage *to* prevent thrombosis in the vein of the inactivated *muscle* Castrocnemius neurectomy weakens the calf but it enables the patient to walk five *or* ten times far*ther than* before and is of great value in the aged, incapacitated *patient* with good *peripheral* nutrition.

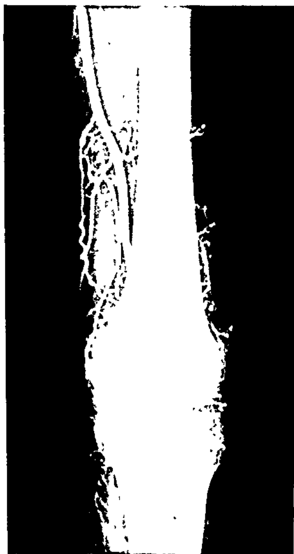

Fig. 15-35. Wasp-waist constriction of popliteal artery, free from atheroma and ideal for endarterectomy.

Better results are obtained in the iliac vessels, but here grafts are preferable except in the case of local obstructions (Fig 15-36)

Technique. The principle of thromboendarterectomy is to remove the obliterated segment through a plane of cleavage in the media Thus the atheromatous plaques and thrombus are removed along with the intima and media out to but not including the external elastic lamina The adventitia and the outer layer of the media remain as the vessel wall. Although the remaining artery wall is attenuated it is capable of withstanding the arterial blood pressure without aneurysm formation. Long-term anticoagulant therapy, for years if necessary, will ensure that recurrent thrombosis is rare

The artery is exposed through a long skin incision overlying the thrombosed segment A longitudinal incision is made into the vessel wall after establishment of proximal and distal control of the patent portions of the vessel by means of bulldog clamps. Careful blunt dissection with a MacDonald dissector will develop a plane of cleavage in the media. The thrombus can then be easily stripped up and down the vessel. Bleeding from collaterals is controlled by means of small bulldog clamps Once the offending thrombus is removed, the intima of the proximal and distal portions of the vessel must be stitched to the vessel wall in order to prevent dissection and thrombosis. The vessel wall is carefully sutured with No. 00000 arterial silk and the clamps are removed. Multiple short incisions may be made, rather than a single long one, and special strippers may be used to mobilize the thrombus, but when this is done there is an implication that too long a segment is being disobliterated. The incision is closed without drainage and heparin is started 6 hours postoperatively. Long-term anticoagulant therapy is commenced the next day with a Dicumarol derivative and is continued for months or years to minimize recurrent thrombosis.

BLOOD VESSEL GRAFTS. The materials available for arterial grafting are autogenous veins,

Fig. 15-36. Local obstruction in common iliac artery; ideal for endarterectomy.

Below-knee When a transmetatarsal amputation has failed, or if gangrene involves the heel or dorsum of the foot, or if uncontrollable infection of the foot or tendon sheaths is present, the only problem is whether or not the stump of an amputation below the knee will heal The knee joint should be preserved at all costs, particularly if the other leg may be lost, as it greatly assists the patient to get in and out of bed and to change position, and favors rehabilitation and the management of a prosthesis Arteriography may help the decision, as it may show collateral vessels going below the knee when the popliteal pulse cannot be felt. Sometimes, the final decision is deferred until the time of operation when the amount of bleeding on incising the muscles will aid the surgeon in deciding upon the ultimate viability of the flaps. Better control of infection, more frequent use of simultaneous sympathectomy, and better techniques, make this amputation the one of choice

With the patient under general anesthesia, without using a tourniquet, and as gently as possible, equal flaps are raised to leave a 5-in tibial stump. The muscles and tibia are sawed through at this level and the fibula is divided 1 in. proximally. The subcutaneous crest of the tibia is beveled, all vessels are caught and tied, and the nerves are separately divided after they have been pulled downward and then allowed to retract. A soft corrugated drain is left in and the skin edges approximated with interrupted silk sutures A firm pressure dressing is applied The drain is removed after 48 hr and the patient is allowed to ambulate on crutches and commence physical therapy on the third day This procedure improves morale and ensures that flexion contracture will not occur.

Above-knee When gangrene or infection extends too high to permit the fashioning of adequate below-knee flaps, when the blood supply below the knee is inadequate, and when a below-knee amputation fails, then an operation at a higher level is necessary. An above-knee amputation is usual when the femoral artery is not palpable and also when gangrene follows an acute embolism or thrombosis because adequate collateral circulation has not had time to develop.

The same general principles as outlined for a below-knee amputation hold. The anterior flap raised is slightly longer than the posterior flap, and the femur is transected to leave a 10- to 12-in stump The deep fascia is raised, with the skin and the muscles divided at the same level as the bone All bleeding points are meticulously controlled The sciatic nerve should be ligated with catgut, as it usually contains a large collateral vessel The muscles are approximated over the end of the bone, the flaps of deep fascia are apposed and the skin is gently closed with interrupted silk sutures after a through-and-through corrugated drain has been inserted between fascia and muscle A pressure bandage is applied The drain is removed after 48 hr Again, early ambulation and physical therapy are encouraged, and a pylon for walking is applied within a few weeks so that the patient does not lose his morale and his balancing powers.

The *Stokes-Gritti* amputation is one that every surgeon should keep in mind as it is especially applicable to the elderly patient in poor general condition It can be performed in 15 min. with almost no blood loss, since only skin is cut. A curved incision beginning at the adductor tubercle crosses the tibia at its tubercle and incorporates the patella in this flap A transverse posterior incision joins the opposite end of the first incision over the outer condyle of the femur. The leg is disarticulated through the knee and the major vessels caught in the popliteal fossa The femur is sawed through at the level of the adductor tubercle and the joint surface of the patella is sawed off and sewed to the

Amputations of the upper extremities are seldom needed in occlusive vascular disease and then usually in thromboangiitis obliterans They need no special consideration here but are managed along the same general principles as those followed for lower-limb amputations.

Fig. 15-37. Healed amputation sites of two toes removed for diabetic gangrene.

TENOTOMY. Although tenotomy of the Achilles tendon is advocated in some clinics, the author does not recommend it, since it is disabling and a patient who has undergone bilateral tenotomy needs a cane to maintain his balance.

While the patient is under general anesthesia, the tendon is divided by inserting a tenotomy knife into the medial side of the ankle just above the insertion of the tendon into the os calcis. There is no bleeding and the skin need not be sutured. The patient walks the next day, and can walk slowly (or perhaps better shuffle) for long distances without pain. If both sides are treated they should be tenotomized at an interval of several months. There is a tendency to reconstitution of the tendon with fibrous tissue but usually without recurrence of claudication. The procedure often cripples the patient, who then needs a cane to maintain his balance and must assume a shuffling gait. Tenotomy should never be performed in the presence of severe ischemia, as infection severe enough to necessitate amputation may ensue, and has been seen by the author.

AMPUTATION. When the blood supply to a limb fails, death of tissue results. Whether this *gangrene* is "wet" or "dry," removal of the dead tissue is necessary. The onset of gangrene may be delayed by medical measures and by encouraging the collateral circulation through sympathectomy. Occasionally, amputation is necessary even in the absence of overt gangrene, because of spreading infection, severe rest pain, or ischemic neuritis. Amputations should be as conservative as possible —that is, as low as is compatible with healing by first intention but as high as necessary to provide a functional stump. This is most important in the elderly patient, not only for psychological and mechanical reasons, but also because, the higher the level of amputation, the higher the mortality rate. Local anesthesia and tourniquets must never be used and tissues must be handled gently.

The techniques of the amputations are standard and will be discussed but briefly. Four levels of amputation are in general use in treating occlusive vascular diseases: digital (usually toes), transmetatarsal, below-knee, and low-thigh.

Digital. When gangrene is localized, well demarcated, and not spreading, then one or even two toes may be safely removed (Fig. 15-37). General anesthesia is used and a circular incision is made around the base of the toe, which is disarticulated at the metatarsophalangeal joint. The cartilage of the metatarsal head should be nipped away with a rongeur, otherwise sequestration may occur. The skin is loosely apposed with one or two interrupted silk or wire stitches. In diabetics, where infection may have spread to the tendon sheath and perhaps even caused osteomyelitis of the metatarsal bone, the affected toe and its metatarsal are removed, and a long plantar incision is used to ensure adequate drainage. Again, the tissues are loosely approximated or they may even be packed loosely with petrolatum gauze and allowed to heal by second intention under adequate antibiotic cover and diabetic control. If there is any doubt about the healing, local amputation is combined with sympathectomy.

Transmetatarsal. When several toes are gangrenous, amputation through the foot is preferable. Again, if the gangrene is well-demarcated to the toes, with no (or minimal) extension to the foot and controlled infection, the best results will be obtained. The presence of at least one pulse at the ankle will ensure success. Lumbar sympathectomy performed simultaneously will increase the number of successful results. The author had most success with this procedure in younger diabetics and in cases of gangrene which followed acute arterial occlusion. A long plantar flap and a transverse dorsal flap are used. The latter is not undermined but carried down to the metatarsal bones, which are divided individually proximal to their heads by means of a Gigli saw. The tissues are handled gently and careful hemostasis permits the surgeon to close the wound with interrupted silk stitches, without drainage and without tension. Little is lost by attempting this procedure since it is the only major amputation after which an amputee can walk without crutches or a prosthesis.

Below-knee. When a transmetatarsal amputation has failed, or if gangrene involves the heel or dorsum of the foot, or if uncontrollable infection of the foot or tendon sheaths is present, the only problem is whether or not the stump of an amputation below the knee will heal. The knee joint should be preserved at all costs, particularly if the other leg may be lost, as it greatly assists the patient to get in and out of bed and to change position, and favors rehabilitation and the management of a prosthesis. Arteriography may help the decision, as it may show collateral vessels going below the knee when the popliteal pulse cannot be felt Sometimes, the final decision is deferred until the time of operation when the amount of bleeding on incising the muscles will aid the surgeon in deciding upon the ultimate viability of the flaps. Better control of infection, more frequent use of simultaneous sympathectomy, and better techniques, make this amputation the one of choice

With the patient under general anesthesia, without using a tourniquet, and as gently as possible, equal flaps are raised to leave a 5-in. tibial stump The muscles and tibia are sawed through at this level and the fibula is divided 1 in proximally. Physiology of systemic arteriovenous fistulas

HARRY A. BLISS

The establishment of a large communication between a systemic artery and vein results in a number of complex reactions on the part of the organism Modern research in this area began after World War I, when gunshot wounds produced arteriovenous fistulas in many soldiers. The work of Matas, Lewis and Drury, Reid, Holman (1937), and others emerged from this era Traumatic fistulas from World War II and the Korean conflict provided further impetus to research

Results of this work have not only afforded insight into the circulatory changes due to arteriovenous fistulas, but have also provided data on the control of cardiac output, blood volume, and renal excretion of salt and water The subject will be discussed first in terms of the acute adjustments to opening or closing a fistula, and, second, in terms of the changes resulting from more long-standing lesions and their surgical eradication.

ACUTE ADJUSTMENTS TO AN ARTERIOVENOUS FISTULA

Opening a large fistula between a systemic artery and vein creates an avenue of lower resistance through which arterial blood readily passes. A portion of this blood proceeds distally to perfuse the limb, but *the larger part seeks the low resistance of the proximal vein and thus quickly returns to the heart* The quantity of blood taking this short circuit back to the heart is determined by the cardiac output and by the inflow resistance of (1) the artery itself, (2) the fistula, (3) the vasculature peripheral to it, and (4) the proximal vein and its central connections These parameters are influenced by (1) the ability of the heart to increase its output, (2) blood viscosity, (3) arterial distensibility, (4) the size and shape of the fistula, (5) venous tone and volume, and (6) the resistance to filling of the right heart. These factors and the measurable quantities reflecting them are discussed below.

Arterial Blood Pressure. When an arteriovenous fistula is suddenly opened, systolic, diastolic, and mean blood pressures drop significantly during the first two beats. After this, pressures tend to return toward normal. Diastolic pressure often recovers less than systolic pressure, so that the pulse pressure may widen Mean pressure, recorded over a period of minutes after fistula opening, shows no change or fall, and occasionally it may actually rise The factors related to these changes in mean blood pressure are discussed below.

HEART RATE. The sudden fall in heart rate upon manual occlusion of arterial inflow to an arteriovenous fistula was first noted by Nicoladoni and Branham This observation has subsequently been confirmed by many workers, both in human beings and in animals. Matas noted that the Nicoladoni-Branham sign may disappear when congestive failure occurs Atropine usually prevents the fall in heart rate without materially changing the blood pressure rise, which invariably occurs It has therefore been postulated that a *vagal reflex*, mod-

erated through the effect of the elevated blood pressure on the aortic and carotid sinus pressoreceptors, causes the bradycardia

The sudden formation of an arteriovenous fistula may cause a rise in the heart rate in animals given the lesion acutely, but this change is not invariable. The latter fact, plus the possibility of a *Bainbridge reflex* causing tachycardia through an increase in right atrial filling, led Coleridge and Linden to reevaluate the mechanism of this phenomenon in dogs.

Keeping the mean blood pressure constant by means of small arterial transfusions during a gradual opening of the fistula, these investigators found that heart rate rose nonetheless. Reasoning that increased pulse pressure might be instrumental in increasing pressoreceptor activity, they occluded the carotid arteries proximal to the carotid sinus Heart rate still increased in half of the animals when the fistula was opened. Although right atrial pressure always rose immediately upon fistula opening, it frequently fell to control levels over a period of minutes, although the elevated heart rate persisted. Curiously, the heart rate response to opening the fistula was abolished when the control heart rate was sufficiently rapid to prevent the occurrence of sinus arrhythmia. Coleridge and Linden concluded that the mechanism of increased heart rate on opening an arteriovenous fistula remained unknown, but that increased venous return, by reducing vagal tone in an unknown way, might be, at least partially, responsible.

THE HEART, CARDIAC OUTPUT, AND BLOOD VOLUME. An immediate rise in cardiac output following the opening of an arteriovenous fistula has been frequently observed The ratio of the short-circuit flow through the fistula to the increase in cardiac output bears an obvious relation to the adequacy of the circulation in general and to the work of the heart in particular.

Frank and his coworkers investigated the determinants of this ratio in an ingenious dog preparation in which short-circuit (shunt) flow could be altered at will They found that the amount of increase in cardiac output was a function of the shunt flow [illegible]
outp[illegible]
sever[illegible]
20 per cent of the control cardiac output, flow through the fistula was equal to the increase in cardiac output [illegible]
peripheral [illegible]
therefore [illegible]

shunt flow was more than 27 per cent of the control cardiac output, however, cardiac output increased by less than the amount of the shunt flow. This reduction in blood flow to the remainder of the body (body flow) resulted in vasoconstriction, elevating systemic peripheral resistance in all animals In those with less severe shunts, this vasoconstriction was sufficient to maintain mean arterial blood pressure at the control level With larger fistulas, however, blood pressure fell despite vasoconstriction.

In the last-mentioned group of animals, 100 ml of isotonic saline solution was administered intravenously while the fistula remained open. A large rise in cardiac output, mainly directed into increasing body flow, ensued. Systemic peripheral resistance fell sharply and mean blood pressure reached control levels. The increase in cardiac output above control was now equal to the shunt flow. In one animal, a continuous infusion of 100 ml of saline solution over a 10-min period allowed a shunt flow equal to 77 per cent of the control cardiac output to be attained as well as a similar percentage increase in cardiac output, so that blood pressure and systemic peripheral resistance were maintained at constant levels.

These experiments appear to demonstrate that, *with small arteriovenous fistulas*, the increase in cardiac output can equal the shunt flow and systemic vasoconstriction, at least on the arterial side of the circulation Cardiac output probably increases, partly through increased ventricular emptying, and partly through mechanisms tending to force venous blood toward the heart These mechanisms may consist of system c venoconstriction or an increased venous volume, although the origin of the latter is unclear

With larger fistulas, these workers conclude that there is a pressure gradient between the fistula and the heart, insufficient to maintain the ratio of 1 between the increase in cardiac output and shunt flow In their view, it is inadequacy of venous return, occasioned by inability to maintain the requisite heartward venous rate of flow, that is primarily responsible for the reduction in body blood flow

Whatever the mechanism involved, it is apparent that, in arteriovenous fistulas, an increase in blood volume makes an important contribution to maintaining blood pressure and flow to the rest of the body.

As Frank et al. point out, there is little evidence that the failure to maintain body flow

simultaneously with large shunt flows is due to the inability of the heart to meet the increased load placed upon it. Even in the group of animals with the largest fistula flows, the increase in central venous pressure was small, averaging 8 mm H_2O. Other workers also found very little or no rise in right atrial pressure after acutely opening an arteriovenous fistula. Indeed, the heart becomes smaller for the first few hours after establishment of the fistula, despite the undoubted increase in cardiac work noted in the early investigation of Gley and Gomez, which were confirmed more recently.

Pulmonary arterial and left atrial pressure show a slight but definite rise when a fistula is acutely opened Probably this has the same significance as the slight rise in right atrial pressure

Renal Function. Hilton et al. found an immediate decrease in renal plasma flow and rate of sodium excretion in each of 10 dogs with an acute arteriovenous fistula. Nine of ten animals showed reduction in urine flow and in glomerular filtration rate. Filtration fraction rose in all dogs, presumably as a result of efferent arteriolar constriction. These observations suggest a possible mechanism for the salt and water retention seen in patients with chronic arteriovenous fistula This retention contributes to the increased blood volume which helps compensate for the altered hemodynamics in these individuals

Local Hemodynamics. The formation of an arteriovenous fistula sufficiently large to be visible by angiography always produces a characteristic continuous murmur and thrill, according to Edwards and Levine, who have described the characteristics of this murmur in detail. Presumably the murmur is produced by turbulent blood flow through the fistula It can be obliterated by occlusion of either the proximal artery or vein

The pressure/flow relationships in the two arterial and two venous tributaries of the fistula are highly variable They depend on the cardiac output and on the resistance factors previously mentioned If the fistula is large, or if the cardiac output is for any other reason inadequate to provide normal body flow, vasoconstriction in the limb bearing the fistula will further decrease blood flow distal to the shunt This effect sets the stage for the pallor, coolness, and occasional gangrene of extremities the blood supply of which is acutely compromised by a sizable arteriovenous fistula. The great elevation of distal venous pressure produces prompt and obvious edema

Schenk et al. have recorded pressure and flow in the four limbs of acutely established femoral and carotid arteriovenous fistulas in dogs. They found that inflow to the distal extremity passes through the distal vein rather than the artery. Holman and Taylor noted similar effects, and added the information that, with larger fistulas, flow in the distal artery is definitely *toward the fistula* Furthermore, they noted that ligation of the proximal vein results in extreme swelling of the extremity. No swelling occurs when the distal vein alone is tied off. Distal artery ligation prevents development of the extensive collateral circulation discussed below.

CHRONIC ADJUSTMENTS TO AN ARTERIOVENOUS FISTULA

The hemodynamics of a chronic arteriovenous fistula differ from those of the acute lesion because of the gradual occurrence of several important effects. These primarily relate to the heart, the blood volume, the kidney, and the local circulation distal to the fistula.

The Heart, Cardiac Output, and Blood Volume. Many observers have substantiated the presence of increased cardiac output in patients and animals with chronic arteriovenous fistula. This elevation is reduced, but generally not eliminated, on manual occlusion of the proximal artery or vein or when the surgeon eradicates the fistula. Many days may elapse after surgery before cardiac output returns to normal levels.

Similarly, most investigators, using serum-albumin-tagging dyes, have found an increase in plasma volume, and, indirectly, in blood volume in nearly all individuals with chronic arteriovenous fistula. Epstein et al (1955), using P^{32}-tagged red blood cells, found no increase in total red-cell mass in dogs 2 to 6 weeks after the creation of an aorta–vena cava shunt A large increase in Evans blue volume occurred in all animals.

These findings indicate that the increase in blood volume occurs through a rise in plasma volume only. The work of Lillehei et al., dem-

onstrating a rise in thiocyanate ("extracellular fluid volume") space in dogs with chronic arteriovenous fistulas, lends support to this conclusion. Furthermore, both the latter authors and Holman found a gradually falling hemoglobin concentration and hematocrit reading in such preparations.

After surgical correction of the arteriovenous communication, the plasma volume gradually falls but, like cardiac output, may require days to attain normal levels.

After the early decrease in heart size, when an arteriovenous fistula is established, *the heart gradually dilates and hypertrophies* The degree of enlargement probably depends on the degree of increase in blood volume, cardiac output, and cardiac work, and on the ability of the heart to meet this increased demand.

Right and left atrial pressures, left ventricular end-diastolic pressure, and pulmonary arterial pressures rise, even in the absence of apparent cardiac failure Heart rate remains elevated Arterial diastolic pressure is usually less than normal, although mean pressure is not greatly affected. On manual occlusion of the artery leading to the fistula, or when the latter is surgically eradicated, all these pressures move in the direction of normal, except mean arterial pressure, which rises above normal The heart shadow may increase in size for 24 hr at this time It then gradually becomes smaller over a period of days to weeks

Heart Failure. Among the earliest reports of progressive congestive heart failure secondary to arteriovenous fistula are those of Stewart and of Sir William Osler. This clinical situation is now well recognized and is often classified in the syndrome of "high-output" congestive failure, along with the heart failure seen in anemia, beriberi, and certain other diseases Dyspnea, pulmonary edema, ascites, peripheral edema, and hepatomegaly may all occur

Matas found evidence of severe chronic myocardial insufficiency in approximately half of his 31 patients with arteriovenous fistulas, many of long duration On the other hand, death from cardiac failure has been reported as early as 4 days after occurrence of the injury causing the fistula As one might suspect, patients with very large shunts who are seen early may suffer from symptoms more suggestive of shock than of congestive heart failure Presumably inadequate compensatory blood-volume adjustment and low body blood flow play major roles in producing this situation

In general, congestive failure is more likely to occur in (1) older patients with long-standing arteriovenous fistulas; (2) individuals with other types of heart disease; and (3) those with large shunts located close to the heart Surgical elimination of the fistula promptly relieves the symptoms of heart failure and results in complete cure

Since plasma volume and interstitial-fluid volume increase in nearly all patients with chronic arteriovenous shunts without congestive heart failure, one may inquire whether inadequate myocardial performance forms the basis for the larger increases in these distribution volumes in patients with arteriovenous fistula and gross edema The answer to this question is not entirely clear. Evidence exists, however, that edematous patients and animals with arteriovenous fistulas have reached the upper limit of the heart's pumping capabilities. After producing aorta–vena cava fistulas, Epstein and Ferguson found many dogs showed rales, weakness, and ascites over a period of several months. When these animals were given blood or saline-solution infusions, cardiac output and work either fell or showed inadequate rises, despite elevation of left ventricular end-diastolic pressure Therapeutic doses of lanatoside C did not affect these abnormalities These apparently maximum levels of cardiac output and work were not significantly different from the maximum levels observed in normal dogs similarly infused.

Campbell reported similar findings in acutely exercised patients with arteriovenous fistulas Patients without congestive heart failure were able to increase cardiac output under stress, but those with this syndrome showed a decrease in cardiac output during exercise.

These responses, in addition to the renal-function abnormalities cited below, are remarkably similar in patients with "high-output" and with "low-output" cardiac failure. This lack of fundamental difference between the two groups suggests that the level of cardiac output is less important than its inadequacy to fill the arterial bed and provide normal organ perfusion, especially in the kidney. Consequent

abnormal renal sodium and water retention, probably aggravated by increased *aldosterone* excretion, result in the edema seen in these patients.

Thus, in any sizable arteriovenous fistula, increases in cardiac output and plasma volume together maintain body blood flow. When the maximum cardiac output has been achieved, further increases in plasma volume occur, with sufficient sodium and water retention to cause edema. The syndrome of congestive heart failure in these patients may, therefore, be thought of as an extension of the normal adaptive response.

Renal Function. In patients with arteriovenous fistula without congestive heart failure, Epstein (1953) found normal renal hemodynamics. When the inflow artery to the fistula was manually occluded for 20 to 50 min, a significant increase in sodium excretion occurred without change in renal plasma flow. No change in sodium excretion took place when the artery was similarly occluded after surgical eradication of the fistula. Epstein concludes that a regulatory mechanism, sensitive to the degree of arterial filling caused the observed rise in sodium excretion This mechanism may be, at least partly, responsible for decreased sodium excretion in patients with arteriovenous fistula and other diseases

Local Hemodynamics. If the arterial and venous tributaries of an arteriovenous fistula are surgically closed within days or weeks after the causative trauma, gangrene of the limb may ensue. Blood flow in an extremity bearing such a fistula is distinctly subnormal in this early period.

During the months and years following establishment of the fistula, however, an extensive distal collateral circulation develops. Lewis (1940) found with each passing year that the involved extremity became warmer and blood flow distal to the fistula increased until it became larger in the involved extremity than in the opposite normal one The limb hypertrophies and remarkably large superficial and deep venous channels often develop Four-point ligation of the fistula may be performed with impunity when collaterals have developed.

Lewis believed that collateral-circulation development occurred in response to ischemia distal to the fistula. Holman (1952) vigorously opposed this conclusion. He constructed femoral arteriovenous fistulas in dogs with thigh amputations in the extremity bearing the fistula. The distal artery was ligated except for a few small branches. Nonetheless a large collateral circulation developed, far beyond the needs of the tissues. In both patients and animals with large arteriovenous fistulas distal-artery blood flow is in the direction of the fistula by the time collaterals have developed. If both the proximal artery and vein are clamped at this time, distal arterial pressure is approximately systemic, a finding demonstrating sizable communications between the latter vessel and other arteries Holman concludes that collateral development depends on the relative size of the fistula and the proximal artery. When the fistula is large, collaterals develop because blood from branches of other arteries distal to the fistula seeks the low resistance outlet of the fistula through their anastomotic connections with the distal artery Prior to adequate collateral development, the limb thus depends on blood flow through the distal vein for its nutrition. By eliminating this channel, early four-point ligation of the aneurysm jeopardizes viability of the extremity. Evidence of collateral circulation should therefore be present before surgery is undertaken.

Circulation time in arteriovenous fistula

WILLIAM M. HITZIG

In arteriovenous fistula, pronounced systemic circulatory effects are produced; their intensity depends upon the size of the fistula and its proximity to the heart. As a consequence of the shunt, *circulating* blood volume is increased, and the increased venous return becomes translated into an augmented cardiac output. Through the medium of compensating peripheral mechanisms, in which vasodilatation plays a dominant role, blood flow may accelerate to aid in establishing a balance between an increased venous return and an increased cardiac output. The circulation time may remain *normal* or may be disproportionately *reduced*. Such reduction occurs only in the early stage of overcompensation before myocardial fatigue and heart failure appear. When, in arteriovenous fistula, progressive failure of the circulation develops, the circulation time reveals either retardation of blood flow or relative acceleration. In the decompensated stage of arteriovenous fistula, it is not unusual to find a circulation time still within the upper limits of normal. Apparently cardiac output, although it is diminished, is still higher than normal

abnormal renal sodium and water retention, probably aggravated by increased *aldosterone* excretion, result in the edema seen in these patients.

Thus, in any sizable arteriovenous fistula, increases in cardiac output and plasma volume together maintain body blood flow. When the maximum cardiac output has been achieved, further increases in plasma volume occur, with sufficient sodium and water retention to cause edema. The syndrome of congestive heart failure in these patients may, therefore, be thought of as an extension of the normal adaptive response.

I

Clinical picture and treatment of systemic arteriovenous fistulas

LEO M. ZIMMERMAN

As an outgrowth of the rapid expansion of surgery of the heart and arterial system, shunts between the right and left circulations are playing an increasingly important part in the diagnosis and management of cardiovascular malformations and diseases The first form of vascular shunt to be recognized, and the one most intensively studied, is *acquired arteriovenous fistula* This abnormal communication was first described by William Hunter (1757), whose case resulted from a simultaneous penetration of a vein and artery during the act of blood letting

Five years later, Hunter found a second case of similar origin, and made this perceptive commentary on the pathogenesis and manifestations of the condition

> In a former paper upon the Aneurysm, I took notice of a *species* of that complaint, which so far as I know, had not been mentioned by any author, viz where there is an *Anastomosis* or immediate communication between the artery and vein at the part where the patient had been let blood, in consequence of the artery being wounded through the trunk of the vein, so that blood passes from the trunk of the artery into the trunk of the vein, and so back to the heart
>
> ° ° °
>
> It will differ in its symptoms from the common spurious Aneurysm principally thus The vein will become dilated or become varicose, and it will have a pulsatile jarring motion, on account of the stream from the artery It will make a hissing noise, which will be found to correspond with the pulse, for the same reason The blood of the tumor will be altogether, or almost entirely fluid, because kept in constant motion. The artery, I apprehend, will become larger in the arm, and smaller at the wrist, than it was in the natural state, which will be found out by comparing the size and the pulse of the artery in both arms at these different places. The reason of which I will speak of later . . And the dilatation of the veins may also vary on account of the size of the artery that is wounded, and of the size of the orifice in the artery, and in the vein

Since this initial and graphic description, this form of arteriovenous shunt has been extensively investigated by numerous workers here and abroad. Of the many who have contributed to an understanding of the altered physiology in arteriovenous fistula, E Holman should be given particular mention. During the greater part of his scientific and surgical career, he has devoted himself to the study of the surgical physiology of this lesion More than any other person he has carried the problem to the experimental surgery laboratory Much of our knowledge of the circulatory effects of arteriovenous fistula in particular, and of cardiovascular shunts in general, has come from the animal studies of Holman More recent investigators have confirmed, amplified, and quantitated his findings with refined investigative methods

Arteriovenous fistula is an abnormal communication between an artery and a vein Such abnormal communications may be congenital or acquired, only the acquired forms will be

considered here. These are usually of traumatic origin, surgical or otherwise, although spontaneous fistulas occasionally develop as a result of vascular disease, including syphilis, atherosclerosis, or embolic infections Most of the traumatic fistulas occur in the extremities, although they may be found in the visceral vessels and in the great vessels of the chest or neck. Penetrating injuries, particularly gunshot or stab wounds, are commonly the cause of fistulas, and the high-velocity missile wounds of modern warfare have furnished an ample number of such lesions for study in recent decades.

REGIONAL HEMODYNAMICS

Dilatation of the arterial and venous trunks proximal to an arteriovenous fistula was observed by Hunter and studied in detail by Holman The work of Schenk et al revealed that the forward flow was markedly increased in the artery proximal to the shunt. In the proximal vein, the forward flow was similarly augmented, and had taken on a pulsatile character *The distal artery*, on the contrary, *showed* a to-and-fro flow of equal volume, with an absence of mean arterial flow. In the distal vein, *the flow was reversed*, away from the heart Pressure relations in these experiments were as follows In the proximal artery the mean pressure dropped slightly (from 160 to 150 mm Hg) and the pulse pressure somewhat decreased. The distal artery showed a marked reduction in diastolic, systolic, and mean pressures Pressures in *the proximal vein* varied according to the proximity to the fistula, the augmented pressure *from the arterial limb* becoming rapidly lost in the distensible venous bed The pressure in the distal vein equaled that in the distal artery

The absence of consistent hypertension in the preatrial portions of the venae cavae and in the atria themselves has been discussed. In addition to the distensibility of *the proximal* venous bed, the reduced diastolic filling pressure of the right ventricle enables it to receive large volumes of blood without sustaining tricuspid insufficiency and atrial hypertension

The local circulation of the extremity which harbors an arteriovenous fistula reflects the above-described flow and pressure changes. The fistulous opening competes with the capillary bed for the available blood brought to the part by the proximal artery. The relative adequacy of the distal circulation is determined by the volume deflected, and this, in turn, by the size of the opening

Pauporte and his coworkers studied the blood turnover rates in the thigh and the tibia by means of a *radioactive dye* (I^{131} *rose* bengal) and an external gamma-ray detection system, in animals with femoral arteriovenous fistulas. The values in the thigh were inconclusive because of the to-and-fro flow, as was described above. In the tibia, however, the blood turnover rate was reduced, and the degree of reduction was proportional to the size of the fistula With the passage of time, the flow tended to return to normal This tendency toward spontaneous improvement was noted by Holman and others, and is presumably affected by an increasing collateral circulation The phenomena attendant upon collateral vasculature will be commented upon later.

The venous trunk, receiving the blood flow through the fistula under arterial pressure, becomes dilated both proximally and distally. Stretching of the lumen of the veins beyond the closing capacity of the valves leads to *valvular incompetence* and *formation of varicose veins*. The sequelae of venous insufficiency, edema, and dermatosis are likely to develop.

EFFECTS OF COMPRESSION OR CLOSURE OF THE FISTULA

Compression of an arteriovenous fistula instantly stops the flow of blood through the parasitic circuit, and the physiologic alterations are reversed William Hunter, in his original description of this condition, noticed that *compression of the fistula* or of the proximal *artery abolished* the thrill and bruit. Nicoladoni (1875), while recording a pulse tracing in the presence of an arteriovenous fistula, observed *an abrupt slowing* of the heart rate when the fistula was occluded by digital compression.

Fifteen years later (1890), Branham made *the* following statement:

> The most mysterious *phenomenon* connected with this case (of an arteriovenous *fistula*), one which I have not been able *to* explain myself or to obtain a satisfactory reason for from others, was slowing of the heart's beat when compression of the ... the wound caused the *heart's*

beat to fall from 80 to 35 or 40 per minute, so to remain until the pressure was relieved Compression of the sound limb produced no such effect Attending the slowing of the heart was a slight dizziness and some dyspnea Examination of the heart showed it to be free from valvular trouble.

This bradycardia, known now as *the Nicoladoni-Branham sign*, or more familiarly as the Branham sign, is pathognomonic of arteriovenous fistula. Slowing of the pulse is accompanied by an elevation of the systolic and diastolic arterial pressures resulting from the elimination of the low peripheral resistance through the shunt The mechanism involved, whereby elevation of the arterial pressure causes slowing of the heart beat (Marey's law), is a vagal reflex originating in pressure-sensitive end organs in the carotid sinus and aortic arch Because this is a vagal effect, it can be abolished by atropine administration. Further alterations in systemic circulatory function occurring after closure of a fistula include reduction in cardiac output and stroke volume The latter is not blocked by atropine (Nickerson et al., 1951b)

Permanent correction of an arteriovenous shunt restores all the circulatory phenomena to normal The blood volume falls, through hemoconcentration and diuresis, within a 24-hr period There is a rapid decrease in heart size and restoration of compensation, provided there are no other cardiovascular abnormalities Only the arterial dilatation persists in long-standing cases, and a late development of aneurysms of the proximal artery has been observed.

COURSE

The natural history of the arteriovenous fistula is determined by the degree of dilatation of the proximal vessels and heart, including the size of the abnormal orifice A vicious cycle becomes established The demand for more blood to "satisfy the appetite" of the fistula leads to the development of collateral vessels which, by augmenting the volume passing through the fistula, tend to further dilate it. This leads to increasing cardiac failure, unless the fistula is surgically closed, until death ensues. One adventitious circumstance, emphasized by Holman, is the restriction of dilatation of the fistula by the formation of cicatricial fibrous tissue. Thus the amount of inflammation may determine the course of changes induced by the fistula.

The development of collateral circulation in the presence of an arteriovenous fistula has been studied in detail by Holman He reported that a richer collateral network is found in the presence of fistulas than in simple arterial aneurysms, or following ligation of an arterial trunk. The reason for this excessive collateral development, chiefly arising *distal* to the fistula, is the low-pressure outflow tract provided by the arteriovenous stoma, which draws blood toward it. Thus, under appropriate conditions, the blood distal to the opening will flow cephalad instead of caudad. Banding or ligation of the artery distal to the fistula prevents the development of the collateral vessels.

Blood Volume and Composition. Increase in the circulating blood volume following the establishment of an arteriovenous fistula has been an accepted phenomenon since it was first reported by Holman (1924). The augmented volume was explained by an initial hemodilution with extracellular fluid, followed by mobilization of the cellular elements from depots in the spleen and liver. The magnitude of the hypervolemia was proportional to the volume of the fistulous diversion of blood A study by Warren et al in a series of patients before and after closure of an arteriovenous fistula showed a significant variation in 44 per cent of the cases and a moderate variation in 56 per cent In general, the elevated volumes were associated with the larger fistulas Investigations by Epstein and Ferguson and others have indicated that the volume increase is largely due to an expanded plasma volume, with little or no change in the total red cell volume The oxygen tension of the venous blood at the fistula site is elevated, approaching that on the arterial side

DIAGNOSIS

The physiologic disturbances incident to a traumatic shunt between an arterial trunk and its accompanying vein are sufficiently apparent to be diagnostic Following an injury to the vessels, usually from penetrating wounds, bleeding and local swelling occur. These, as Hunter observed, may be slight or severe, depending upon the degree of runoff through the vein The characteristic *thrill* and *bruit*, synchronous with the heart beat but more intense in diastole, may not become apparent for sev-

eral days. The *pulsatile swelling, peripheral ischemia*, and *dilatation of the proximal veins* (which may pulsate) are characteristic Venous insufficiency, manifested by *edema, varicosities*, and, later, by pigmentation, dermatoses, and cutaneous *ulcerations* resembling the postphlebitic state, will also occur.

The severity of the circulatory impairment varies with the volume of shunted blood When present, failure is revealed by dyspnea and tachycardia on slight exertion, "pounding" of the heart, cardiac dilatation, and eventual death

Examination reveals the wound or its scar, the pulsatile swelling, thrill and bruit, and the pathognomonic *slowing of the pulse*, and *elevation of blood pressure upon digital occlusion of the shunt* The cutaneous temperature in the region of the fistula is elevated because of the dilatation of both arteries and veins Distal to the shunt, there may be arterial insufficiency with reduced skin temperature Venous engorgement and tortuosity, both proximally and distally, may be noted, as well as edema, dermatoses, and pigmentation. Arteriographic visualization of the fistula is possible but is usually not necessary for diagnosis

TREATMENT

Both the prevention and repair of arteriovenous fistulas have undergone dramatic changes The period in which the newer methods were instituted, with remarkable improvement in the results, coincides with the interval between the end of World War II and the outbreak of the Korean hostilities, and is a reflection of the powerful upswing in arterial surgery Credit for these advances goes primarily to the medical departments of the Armed Forces, which have had to contend with such large numbers of military injuries of important arteries They have responded to the challenge, and the lessons learned are being applied in civilian practice

For many decades, the usually recommended operation for arteriovenous fistula has been the *quadruple (or sextuple) ligation of the arterial and venous trunks proximal and distal to the lesion, and excision of the fistula* In early cases, if the severity of the systemic disturbances permitted, operation was delayed to allow the development of more adequate collateral circulation, and the sufficiency of the vascular supply to permit ligation of the principal arterial trunk was gauged by the reaction in the distal portions to temporary compression of the vessels. Elin (1946) reviewed a series of 340 cases of arteriovenous fistula from World War II, in which only 12 patients had had reparative operations. The remaining 338 had been treated by the usual method of quadruple ligation and excision None of the cases in this series ended in amputation.

A number of subsequent studies reported that although viability of the limb was usually preserved following this operation, the arterial blood supply was inadequate. Herringman (1947) found that vascular insufficiency with intermittent claudication, ischemic pain, numbness, tingling, atrophy of muscles and coldness of the extremity persisted after quadruple ligation, often to a distressing and disabling degree He emphasized that "restoration of normal arterial circulation is the primary objective of the surgeon whenever possible" Similar sequelae were described by Bosher, Harper, and Bigger, despite the added procedure of sympathectomy. In experimental studies, they demonstrated a marked regression of the collateral arterial supply following closure of a fistula. Gerbode, Holman, Dickinson, and Spencer, on the same grounds, also emphasized the desirability of restoring arterial continuity in arteriovenous fistulas, whenever it is technically feasible. Reporting from the Mayo Clinic, Foley et al. stated that a follow-up study of arteriovenous fistula of the lower extremities treated by ligation and excision revealed *arterial insufficiency* of varying degrees of severity in 50 per cent of the patients, and *venous insufficiency* in 75 per cent of the patients

During World War II, the policy of concentrating wounded personnel in special centers for treatment, according to the type of injury, was instituted, and this was continued for the casualties of the Korean War. In the management of vascular injuries, a considerable period elapsed between the time of wounding and the institution of definitive therapy, which necessarily excluded injuries of such severe grade as to make such waiting impossible. The earliest patients to reach the home base because of arterial injuries were treated by the traditional ligation techniques. Subsequently, a changeover to *arterial repairs in all major vascular injuries* was made, with immediate improvement in the results

beat to fall from 80 to 35 or 40 per minute, so to remain until the pressure was relieved Compression of the sound limb produced no such effect Attending the slowing of the heart was a slight dizziness and some dyspnea. Examination of the heart showed it to be free from valvular trouble.

This bradycardia, known now as *the Nicoladoni-Branham sign*, or more familiarly as the Branham sign, is pathognomonic of arteriovenous fistula. Slowing of the pulse is accompanied by an elevation of the systolic and diastolic arterial pressures resulting from the elimination of the low peripheral resistance through the shunt. The mechanism involved, whereby elevation of the arterial pressure causes slowing of the heart beat (Marey's law), is a vagal reflex originating in pressure-sensitive end organs in the carotid sinus and aortic arch Because this is a vagal effect, it can be abolished by atropine administration. Further alterations in systemic circulatory function occurring after closure of a fistula include reduction in cardiac output and stroke volume The latter is not blocked by atropine (Nickerson et al, 1951b).

Permanent correction of an arteriovenous shunt restores all the circulatory phenomena to normal. The blood volume falls, through hemoconcentration and diuresis, within a 24-hr period There is a rapid decrease in heart size and restoration of compensation, provided there are no other cardiovascular abnormalities. Only the arterial dilatation persists in long-standing cases, and a late development of aneurysms of the proximal artery has been observed.

COURSE

The natural history of the arteriovenous fistula is determined by the degree of dilatation of the proximal vessels and heart, including the size of the abnormal orifice A vicious cycle becomes established. The demand for more blood to "satisfy the appetite" of the fistula leads to the development of collateral vessels which, by augmenting the volume passing through the fistula, tend to further dilate it This leads to increasing cardiac failure, unless the fistula is surgically closed, until death ensues. One adventitious circumstance, emphasized by Holman, is the restriction of dilatation of the fistula by the formation of cicatricial fibrous tissue Thus the amount of inflammation may determine the course of changes induced by the fistula.

The development of collateral circulation in the presence of an arteriovenous fistula has been studied in detail by Holman He reported that a richer collateral network is found in the presence of fistulas than in simple arterial aneurysms, or following ligation of an arterial trunk. The reason for this excessive collateral development, chiefly arising *distal* to the fistula, is the low-pressure outflow tract provided by the arteriovenous stoma, which draws blood toward it. Thus, under appropriate conditions, the blood distal to the opening will flow cephalad instead of caudad. Banding or ligation of the artery distal to the fistula prevents the development of the collateral vessels.

Blood Volume and Composition Increase in the circulating blood volume following the establishment of an arteriovenous fistula has been an accepted phenomenon since it was first reported by Holman (1924). The augmented volume was explained by an initial hemodilution with extracellular fluid, followed by mobilization of the cellular elements from depots in the spleen and liver. The magnitude of the hypervolemia was proportional to the volume of the fistulous diversion of blood A study by Warren et al. in a series of patients before and after closure of an arteriovenous fistula showed a significant variation in 44 per cent of the cases and a moderate variation in 56 per cent. In general, the elevated volumes were associated with the larger fistulas. Investigations by Epstein and Ferguson and others have indicated that the volume increase is largely due to an expanded plasma volume, with little or no change in the total red cell volume. The oxygen tension of the venous blood at the fistula site is elevated, approaching that on the arterial side.

DIAGNOSIS

The physiologic disturbances incident to a traumatic shunt between an arterial trunk and its accompanying vein are sufficiently apparent to be diagnostic. Following an injury to the vessels, usually from penetrating wounds bleeding and local swelling occur. These, as Hunter observed, may be slight or severe, depending upon the degree of runoff through the vein The characteristic *thrill* and *bruit*, synchronous with the heart beat but more intense in diastole, may not become apparent for sev-

17

Cerebrovascular attacks

GILBERT H. GLASER

Diseases of the cerebral blood vessels and alterations of blood flow account for numerous acute neurologic episodes and much chronic progressive disturbance of brain function, and represent a major cause of death. A cerebrovascular attack or "stroke" is defined as *a focal neurologic disorder of abrupt development due to a pathologic process involving the vascular supply to the brain, secondary to disease of blood vessels, disturbance of blood flow, or both.* Patients recovering from "cerebrovascular accidents" are becoming an increasingly serious problem in regard to chronic care and rehabilitation. The number of these patients is increasing as the older age group becomes a greater fraction of the population. In 1955, over 175,000 deaths were recorded in the United States because of vascular lesions affecting the central nervous system, and *there are presently close to 2 million victims of cerebrovascular disease extant.* It is becoming increasingly important for the physician to be able to differentiate between the various types of cerebrovascular accidents and to determine the actual location of the involved blood vessels, so that proper initial therapy may be administered. In recent years, several new treatments have been developed, but their effectiveness is still to be evaluated thoroughly, and there is still a great need for better treatments in the acute phase, especially to control further brain damage. Also, considerations of the over-all *prevention of atherosclerosis* are paramount. The proper evaluation of these treatments is based upon a thorough knowledge of the anatomic, physiologic, and pathologic features of the cerebral circulation, and, in addition, upon the proper establishment of therapeutic investigations involving adequate controls.

CLASSIFICATION

There is still no entirely satisfactory classification of cerebrovascular diseases which will take care of both pathologic and clinical features. A classification and outline have been presented by a *Committee of the National Institute of Neurological Diseases and Blindness* (1958) which should stand as a basis for consideration. The term "cerebrovascular attack" refers to involvement of one or more blood vessels of the brain or of their root vessels by a pathologic process, producing an episode of clinical dysfunction. The pathologic process may be an abnormality of the vascular wall, *occlusion* by thrombus or embolus, change in caliber of lumen, altered permeability to plasma and blood cells, and, most important, alteration in blood flow, especially a decrease.

The following working classification of cerebrovascular attacks is modified from that of the Institute's committee.

I. Transient cerebral ischemia without infarction
   A. Recurrent focal cerebral ischemic attack (insufficiency, "spasm")
   B. *Systemic hypotension*, with syncope, focal [illegible]

II. [illegible]
   [illegible]
   A. *Thrombosis* with atherosclerosis
   B. Cerebral embolism, of cardiac or noncardiac origin
   C. [illegible]

On the basis of this experience, the immediate operative repair of vascular injuries was instituted in the Army, Navy and Marine hospitals at the battle fronts. The results proved most gratifying. The necessity for amputation in the entire series so treated fell from the previous level of 48 to 10 3 per cent. It is important that vein injury accompanied the arterial trauma in 63 per cent of the 297 patients treated by immediate surgery, and no instance of arteriovenous fistula was reported in this series (Hughes)

The treatment at the Walter Reed Army Medical Center of arteriovenous fistulas and aneurysms resulting from the Korean conflict also showed striking improvement when reparative methods supplanted the obliterative procedures (Hughes and Jahnke) A total of 215 such fistulas in 202 patients were treated in the Center, and a 5-year follow-up study was made Two-thirds of the lesions were fistulas, one-third aneurysms Most of the cases resulted from the first 2 years of the war, before the immediate repair of arterial wounds had been instituted The authors state· "After repair of acute vascular injuries became an established policy in Korea, the subsequent incidence of aneurysms and fistulas was markedly diminished"

Initially, quadruple ligation and excision was the management employed for the fistulas This entailed a delay of 3 months or longer to allow for the development of collateral circulation. Thirty lesions of major vessels, including both aneurysms and fistulas, were treated by obliterative techniques No amputations became necessary, but many patients developed arterial insufficiency, for which subsequent sympathectomy proved of little value

In order to eliminate the long preparatory period, the need for sympathectomy, and the arterial ischemia, *restoration of continuity of the major vessels* was later used instead of the obliterative methods. Division of the fistula and subsequent suture, anastomosis, or autogenous vein (or preserved artery) grafts were the means of restoring arterial continuity.

Venous insufficiency sometimes resulted from ligating the veins, and in about 30 per cent of the fistulas, simultaneous venous repair was also done. The follow-up was not sufficiently complete to permit accurate evaluation of the end results, but the impression gained was that the reparative methods were definitely to be preferred over the obliterative technique

The lessons learned from the military experience are finding application in civilian life. A striking series of four *aorta–vena cava fistulas* has been recently reported by DeBakey and his associates. Three of these were of traumatic origin, and one was due to a ruptured aneurysm All were successfully repaired, using various methods appropriate to the particular situation This and other similar reports indicate a trend in the management of vascular injuries which should largely eliminate arteriovenous fistula as a sequela. The occasional shunt that may occur, as well as those of spontaneous origin, can now be corrected, with restoration of arterial sufficiency.

Waltz et al, 1959), and hypoglycemia (Meyer et al, 1958).

Certain anatomic and physiologic factors are of importance in considering the preceding pathologic processes, and the most significant of these will be briefly reviewed. The question of *collateral circulation* involving the cerebral arterial trees still has not been completely answered The older concept was that the cerebral arteries were *end arteries* with minimal or no collaterals. Much recent anatomic work has demonstrated that *collateral arterial* circulations exist (Denny-Brown and Meyer, 1957, Meyer and Denny-Brown, 1957, Vander-Eecken and Adams, 1953), but there is still a question about their effectiveness There are at least three major anastomotic systems of vessels. (1) the circle of Willis and occasionally a *precircle connection* between the carotid and vertebral arteries (Fig 15-38), (2) the meningeal arterial anastomoses between the end vessels of the anterior, middle, and posterior cerebral arteries, and (3) an extensive capillary anastomotic network Each of these may serve, under certain conditions, to counteract the effects of focal ischemia. For example, particularly distinct anastomoses have been demonstrated between the ophthalmic and meningeal arteries, and the vertebral and external carotid arteries within 1 to 4 months after occlusion (Lehrer, 1958, Mount and Taveras, 1957). However, since encephalomalacias or relatively large areas of infarction occur in relation to occlusion or vascular insufficiency, and develop acutely, these cerebral collaterals, no matter how rich anatomically, are apparently not adequate to care for the immediate metabolic needs of the brain, and in most instances do not prevent further symptoms and ischemic necrosis. The demands of the cerebral tissue for glucose and oxygen are so great that isolated portions of the brain cannot exist without an almost completely intact circulation, and, when this is decreased to any significant extent, *infarction* usually results This is clinically important because of the vulnerability of specific areas of the brain in relation to specialization of function. The

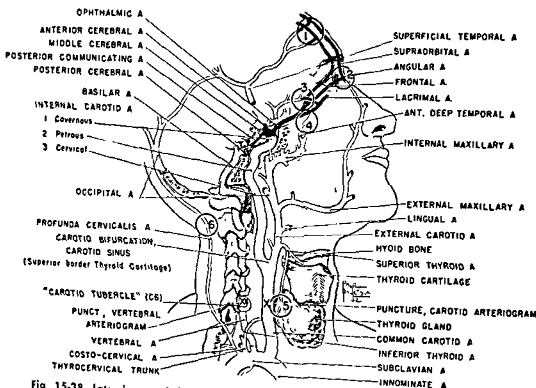

Fig 15-38. Lateral view of the circle of Willis and the cervical and intracranial carotid and vertebral arteries Anastomoses between branches of the internal and external carotid arteries are circled Sites of puncture for carotid and vertebral angiography are indicated (X).   - A. Malignant hypertension
  - B. Acute glomerulonephritis
  - C. Eclampsia

The statistical *incidence of the* various types *of* cerebrovascular attacks varies *according to* the hospital series studied (*Adams, 1954; Brain, 1954; Murphy, 1954;* Gurdjian *et al., 1960*). The statistical incidence of *transient ischemic attacks* in a general *population is not* known as yet. It is believed that *at least 80* per cent of the patients with *cerebrovascular disease* admitted to hospitals have *cerebral infarction*, or *encephalomalacia*. In the past, most of these *patients* were thought to have *experienced* a *cerebral thrombosis*. However, at least one-third of them may have had *cerebral embolization* and only about one-third a *thrombosis of a large artery*. Many patients have *multiple small infarcts*, and in some *patients*, areas of infarction are present *without* evidence of gross vascular occlusion. *Massive cerebral hemorrhage is* present in 10 to 15 *per cent* of the hospitalized patients. This *disorder* may be more common, but because *of the* high *mortality rate*, many of these *patients do not* reach the hospital. About 5 *to* 8 *per cent of* patients in various series have *subarachnoid hemorrhage*. The other small-vessel *diseases* and blood dyscrasias make up the remainder.

PERTINENT ASPECTS OF PATHOPHYSIOLOGY

There has been a gradually increasing emphasis on several special aspects *of the pathophysiology of* cerebrovascular diseases. *Probably the most* important developing *concept* is that of *cerebral vascular insufficiency, hemodynamic crisis*, or *diminished cerebral blood flow* related to extracerebral factors as a *cause* of transient and recurrent neurologic symptoms (Alajouanine et al., *1960*, *Corday et al*, *1953*; Denny-Brown, *1960*; Fisher, *1958a*; Millikan and Siekert, *1955*; Rothenberg *et al.*, *1957*).

This is of particular importance when *one* considers the two emphasized sources of cerebrovascular disorders *with regard to* ves- location: the *internal carotid artery* and *basilar artery* (Denny-Brown, 1951, Fish 1951; Johnson et al., 1951; Kubik and Adam *1946*; Meyer et al., 1960, Millikan and Siekert *1955*) (*Fig. 15-38*). Another source regarde to be significant is *cerebral embolism* (Adam *1954; Fisher and Adams*, 1951; Wells, 1959) *with origin* of the embolization from (1) auricular thrombi, as in rheumatic or arterio sclerotic heart *disease with atrial fibrillation*, (*2*) bacterial endocarditis, (3) myocardial infarction with mural thrombi, and, occasionally, (*4*) atheroma in the aorta *or carotid* arteries with thrombosis It has been emphasized further that the cerebral infarction associated with *cerebral* embolism is usually *hemorrhagic*, whereas the infarction of thrombotic occlusion *is of the anemic* type.

The *totality* of the cerebral blood flow is related *to* factors of blood pressure (hypertension, hypotension, and turbulence), opposition to blood flow by variations in caliber and elasticity of the vascular tree (as produced by *localized* narrowings of the lumen, thrombosis, *embolism*, or extrinsic compression), and inherent characteristics of the blood, such as viscosity. Both generalized and localized alterations *in* blood pressure and blood flow are most significant (Denny-Brown, 1951, 1960) Those pertaining to cerebral vascular insufficiency or to hypotension in the cerebral vascular tree may be related to hemorrhagic shock, myocardial infarction, antihypertensive drugs, *postural* hypotension, the carotid sinus syndrome, anesthetics (especially spinal), cardiac surgery, sympathectomy, traumatic shock, cardiac arrhythmias (such as paroxysmal tachycardia, ventricular fibrillation, and Adams-Stokes syndrome), congestive heart failure, carotid artery ligation, and *the* progressive stenosis and occlusion of the carotid or basilar arteries, which feed the circle of Willis, usually related to atherosclerosis.

This concept of cerebral vascular insufficiency is similar to that often applied to cardiac disease in relation *to acute and recurrent* coronary *insufficiency. Distinction should* be made between carotid and basilar artery insufficiency states *due to local involvement* of these vessels and the partial or total contribution to *the* clinical picture by more general factors. such as systemic falls in blood pressure, severe

observed in man at operation when branches of the circle of Willis or other cerebral arteries were being dissected or otherwise manipulated for their exposure (Fletcher et al., 1959, Pool, 1958). Vasospasm also is regarded to be responsible for the transient "aura" associated with the *migraine syndrome* (Engel et al, 1945). However, recent investigators feel that the best explanation for transient recurring symptoms related to the cerebral circulation in most instances is not spasm but a *chronic intermittent insufficiency*, a *developing occlusion* of the internal carotid and basilar arteries, or *multiple tiny occlusions* within the cerebral substance, their repetition often being due to fluctuation in systemic blood pressure, as indicated above. Since metabolic factors appear to be most significant with regard to the local controls of cerebral circulation, attention has been paid to *hypoxia* and accumulations of carbon dioxide, especially local There are sudden falls in oxygen tension in infarcted areas, these may produce damage to the walls of capillaries and small arterioles, and thus contribute to *distal stasis* of blood cells and small extravasations (Denny-Brown, 1960, Denny-Brown et al, 1957, Meyer et al, 1957) The *Bayliss effect* may also be significant, the rapid falls in internal vascular pressures in the small vessels producing arteriolar dilatation (Bayliss, 1902) and further contributions to "stasis" *Carbon dioxide* is regarded as the most potent cerebral vasodilator (Table 15-12) and may be responsible for further vasodilatation in and around the areas of cerebral infarction Carbon dioxide is accumulated in heavy concentration in these areas and, therefore, it would appear likely that all the vessels in the involved area would be in a state of maximal dilatation This has implications for therapy.

Since our concepts of the pathogenesis and treatment of cerebrovascular disease are to be based on our knowledge of the physiology of cerebral blood flow, a review of certain significant features will be made A great deal of information has accrued concerning the general cerebral blood flow, and measurements have been made under many different circumstances by the Schmidt-Kety technique using the Fick principle (Kety, 1955, Schmidt, 1950) Of importance in these determinations is the consideration that the brain utilizes 20 per cent of the total oxygen consumption and 65 per cent of the glucose uptake of the body at rest, although it represents but 2 per cent of the body weight. The high rate of metabolic activity of the neuron has a heavy oxygen requirement, and it has been determined that if there is a total oxygen lack for, at the most, 8 min, the nerve cell ceases permanently to function and dies (Heymans, 1950) If *hypoxia* is partial, recovery of the neuron may occur even after a period of disturbed function which may have lasted for days The degree of recovery, however, is difficult to determine.

Studies of general cerebral blood flow have given the following normal values for the general cerebral circulation and metabolism in healthy young men (Kety, 1955, Schmidt, 1950), expressed as per 100 Gm/min: (1) cerebral blood flow (CBF), 54 ml, (2) cerebrovascular resistance (CVR), 1.6 units, (3) cerebral oxygen consumption ($CMRO_2$), 3 3 ml, (4) glucose consumption, 5 4 mg, (5) respiratory quotient, 0 99. This method has been applied to many experimental and clinical situations, some of these, believed to be highly significant in relation to the problem of cerebrovascular attacks, are presented in Table 15-12 (Kety, 1955). Here, the effects of various drugs, other agents or procedures, and clinical conditions on the cerebral circulation and metabolism are expressed in terms of a percentile change from normal or control values. Changes of possible statistical significance are so indicated, clinical significance, of course, has been [illegible]

[illegible] the effects produced by most drugs on cerebral blood flow are statistically not significant or only slightly so. The agent with by far the greatest effect is *carbon dioxide* It should be realized, however, that these data are gross and are concerned with total cerebral blood flow. Certainly, local changes may be of more importance but, up to the present time, techniques for the [illegible]

in [illegible]

th [illegible]

an [illegible] regulatory mechanism for the cerebral circulation, and local variations in vascular resistance certainly must occur in relation to local lesions, especially infarction The factors contributing to the property of resistance have not been completely evaluated It should be mentioned that the mechanism of action of the various drugs on the cerebral blood vessels is not known This also applies to the effects of carbon dioxide and oxygen The limitations of nerve supply imply that the effects may be intrinsic within the muscular walls, perhaps by local reflex phenomena

In this consideration of general features of pathogenesis, factors of *external compression of cerebral arteries* should be given more atten-

fact, however, that the area of infarction is usually smaller than the area of supply of that particular artery (as has been demonstrated by injection methods) suggests that there are a critical zone and a zone of shared supply. It should be noted that the anatomically significant short penetrating arteries, such as the lenticulostriate and thalamoperforating, have relatively few anastomoses and are the closest to being end arteries Their areas of supply are especially vulnerable to infarction A major question that is still not answered is that of the possible embarrassment of the collateral circulation around an area of infarction by associated "vasospasm"

Many considerations of pathogenesis and therapy center about the possible existence of *cerebral vasospasm* (Byrom, 1954; Denny-Brown, 1951; Fletcher et al, 1959, Pool, 1958). The cerebral arteriolar system is noteworthy because of the lack of significant vasomotor nerve supply and a deficient muscularis. In addition, it has been demonstrated that cervical sympathectomy or stellate ganglion block does not produce significant changes in cerebral blood flow, and that the various drugs which act upon the autonomic nervous system do not significantly alter this flow (Table 15-12, Kety, 1955). It has been shown, however, that the arterioles in the pia contract in experimental embolism, and that this contraction may be abolished by sympathectomy or block (Villaret and Cachera, 1939). This relates only to the superficial arterioles, and apparently not to those in the intracerebrovascular tree. However, so-called *cerebrovascular spasm* of major arteries *has* been demonstrated during arteriography (Fletcher et al, 1959), and widespread spasm of cortical vessels has been observed during experimental renal hypertension in rats with hypertensive encephalopathy (Byrom, 1954). Actual vasospasm has been

If the intracranial pressure is elevated, there

TABLE 15-13 BLOOD SUPPLY TO BRAIN AND SYNDROMES OF CEREBROVASCULAR ATTACKS

Artery	*Area of supply*	*Neurologic syndrome*
Vertebral-basilar	Posterior fossa structures: pons medulla, cerebellum; also posterior cerebral distribution (see below)	Unilateral or bilateral (1) dysfunction of cranial nerves III to XII, especially III, VI, VII, (2) cerebellar disorders, (3) motor and sensory tract signs, (4) blindness Disturbance of consciousness; patchy involvement common
Paramedian	Paramedian base of pons and midbrain, ventral pontine tegmentum	Ipsilateral paralysis of cranial nerves III, IV, VI, contralateral hemiparesis
Superior cerebellar	Lateral tegmentum midbrain, upper pons, cerebellum, middle and superior cerebellar peduncles, roof nuclei of cerebellum, lateral spinothalamic tract, descending sympathetic	Ipsilateral Horner's syndrome, cerebellar ataxia, contralateral pain and temperature deficit of face and body
Anteroinferior cerebellar (lateral pontomedullary)	Anteroinferior cerebellum, lateral tegmentum of pons and upper medulla, middle and inferior cerebellar peduncles, descending sympathetics, nuclei of cranial nerves V, VII, VIII, lateral spinothalamic tract	Ipsilateral cerebellar ataxia, pain and temperature deficit on face, Horner's syndrome, deafness, facial paralysis, nystagmus, and vertigo, contralateral pain and temperature deficit on arm, trunk, leg
Posteroinferior cerebellar (lateral medullary)	Posteroinferior cerebellum, lateral medullary tegmentum, including descending sympathetics, vestibular nuclei, spinal nuclei of cranial nerves V, IX, and X, inferior cerebellar peduncle, lateral spinothalamic tract	Ipsilateral Horner's syndrome, vertigo, nystagmus, pain and temperature deficit on face, cerebellar ataxia, paresis of palate and vocal cord with dysphagia and dysphonia, contralateral pain and temperature deficit on arm, trunk, leg
Internal carotid	Combined supply of anterior and middle cerebral and ophthalmic arteries	Ipsilateral blindness, Horner's syndrome, contralateral hemiplegia, and hemisensory deficit; dysphasia if dominant hemisphere
Ophthalmic	[illegible]	[illegible]
Anterior cerebral	[illegible]	[illegible]
Middle cerebral	Convexity of cerebral hemisphere and white matter, including lateral orbital frontal and temporal tip; perforating branches to internal capsule, caudate and lenticular nuclei, and anterior thalamus	Contralateral hemiplegia and hemisensory deficit; aphasia, agnosia, and apraxia if dominant hemisphere; syndromes often incomplete; faciobrachial monoplegia common
Posterior cerebral	[illegible] ... losum [illegible]	[illegible]

tion since they may contribute to the picture of local insufficiency syndromes (Lindenberg, 1955). The vertebral artery is particularly liable to repeated trauma and constriction by osteoarthritic, spondylitic disease and anomalies such as the *Klippel-Feil fusion of cervical vertebrae* (Ford, 1952; Hutchinson and Yates, 1956, Illingworth, 1956; Tatlow and Banner, 1957). Other anomalies, such as a prominent transverse process of the first cervical vertebra, may be contributory. Symptoms may appear during special postures, particularly flexion and turning (*postural stenosis*, Toole and Tucker, 1960). The possibility of *platelet emboli* from repeated trauma to vascular walls also may be high (Denny-Brown, 1960). *Increased intracranial pressure* may also compress blood vessels secondarily because of *herniation* of brain substance. Herniation of the temporal lobe through the incisura of the tentorium may compress the posterior cerebral artery against this structure, producing a falsely localizing *hemianopsia.* The anterior cerebral artery may be compressed by the cingulate gyrus herniating under the falx cerebri.

Peculiar anomalies of the circle of Willis also should be mentioned as occasional determining factors in the distribution of an infarction These are especially common in the vertebral-basilar system. However, some anatomic compensation does exist, and if one vessel is hypoplastic, certain related vessels may become enlarged and assume compensatory function A posteroinferior cerebellar artery may be absent on one side and compensated for by a large anteroinferior cerebellar artery One vertebral artery is often hypoplastic Hypoplasia of the posterior cerebral arteries is quite common In this circumstance, the posterior communicating artery may be large, and the entire supply of a hemisphere may be from the internal carotid

The areas of distribution of the cerebral vessels and the major clinical syndromes of neurologic involvement present in cerebrovascular attacks are presented in Table 15-13

GENERAL DIAGNOSTIC CONSIDERATIONS

Patients who have had "strokes," or cerebrovascular attacks, should not all be regarded as clinically similar from a diagnostic or therapeutic standpoint These patients often present difficult problems in diagnosis and emergency treatment, as well as in long-term management It is hoped that improved knowledge of differential diagnosis may permit use of special forms of treatment, which may limit the mortality and morbidity, particularly with regard to residual effects. Basically, these patients have had a varying degree of brain trauma and should be treated accordingly. One of the chief initial problems is the diagnosis and treatment of a patient who may be *unconscious or comatose.* Immediate diagnostic considerations are concerned with differentiating the possibility of cerebrovascular accidents from other lesions of the central nervous system, especially brain tumors and metabolic disorders, as well as an effect of trauma, such as subdural hematoma In addition, an attempt should be made to determine the particular nature of the cerebrovascular disease present.

A cerebrovascular disorder is indicated by the sudden appearance of focal or generalized neurologic symptoms in a patient with already existing cardiovascular disease, such as hypertension, arteriosclerosis, or a specific cardiac disorder (myocardial infarction or cardiac arrhythmia). Of great importance is the *history*, which should give an indication of the temporal sequence of events and a dynamic consideration of the pathologic process.

There are many variations in the pattern and severity of cerebrovascular attacks, but, in general, the patterns of development which lead to the clinical status of the patient at the time he is seen by a physician may be regarded as follows (1) *intermittent insufficiency*, transient ischemic attacks, or incipient stroke; (2) *advancing stroke*, with stepwise development (with or without transient ischemic attacks—"stuttering"), transient ischemic attacks progressing to a persistent neurologic deficit, or a gradual slow onset with minor fluctuations, (3) *completed stroke* developing as a single abrupt event in minutes or hours, with or without stuttering fluctuations, in an advancing way as described above, or, as in some instances, a completed stroke with a fixed disability but followed by further transient ischemic attacks

Steady progression of increasing neurologic signs and symptoms over a period of days or weeks without improvement usually indicates not a cerebrovascular attack but an expanding intracranial lesion There are some exceptions, however, as in gradual slow occlusion of ves-

sels The initial diagnostic evaluation should include, therefore, a complete history, physical and neurologic examination, blood count; urinalysis; determination of the blood sugar, nonprotein nitrogen, and electrolytes, x-ray of the skull, electrocardiogram, and an electroencephalogram. The utilization of the *electroencephalogram* in diagnosis and management of cerebrovascular attacks is not mandatory but may be helpful under appropriate orientation. *Cerebrospinal fluid examination* is often extremely important from the diagnostic standpoint but should not be performed routinely. If the intracranial pressure is elevated, there

Herniation of the temporal lobe through the incisura of the tentorium may compress the posterior cerebral artery against this structure, producing a falsely localizing *hemianopsia*. The anterior cerebral artery may be compressed by the cingulate gyrus herniating under the falx cerebri

Peculiar anomalies of the circle of Willis also should be mentioned as occasional determining factors in the distribution of an infarction These are especially common in the vertebral-basilar system However, some anatomic compensation does exist, and if one vessel is hypoplastic, certain related vessels may become enlarged and assume compensatory function. A posteroinferior cerebellar artery may be absent on one side and compensated for by a large anteroinferior cerebellar artery One vertebral artery is often hypoplastic. Hypoplasia of the posterior cerebral arteries is quite common. In this circumstance, the posterior communicating artery may be large, and the entire supply of a hemisphere may be from the internal carotid.

The areas of distribution of the cerebral vessels and the major clinical syndromes of neurologic involvement present in cerebrovascular attacks are presented in Table 15-13

GENERAL DIAGNOSTIC CONSIDERATIONS

Patients who have had "strokes," or cerebrovascular attacks, should not all be regarded as clinically similar from a diagnostic or therapeutic standpoint These patients often present difficult problems in diagnosis and emergency treatment, as well as in long-term management It is hoped that improved knowledge of differential diagnosis may permit use of special forms of treatment, which may limit the mortality and morbidity, particularly with regard to residual effects. Basically, these patients have had a varying degree of brain trauma and should be treated accordingly. One of the chief initial problems is the diagnosis and treatment of a patient who may be *unconscious or comatose*. Immediate diagnostic considerations are concerned with differentiating the possibility of cerebrovascular accidents from other lesions of the central nervous system, especially brain tumors and metabolic disorders, as well as an effect of trauma, such as subdural hematoma In addition, an attempt should be made to determine the particular nature of the cerebrovascular disease present.

A cerebrovascular disorder is indicated by the sudden appearance of focal or generalized neurologic symptoms in a patient with already existing cardiovascular disease, such as hypertension, arteriosclerosis, or a specific cardiac disorder (myocardial infarction or cardiac arrhythmia). Of great importance is the *history*, which should give an indication of the temporal sequence of events and a dynamic consideration of the pathologic process

There are many variations in the pattern and severity of cerebrovascular attacks, but, in general, the patterns of development which lead to the clinical status of the patient at the time he is seen by a physician may be regarded as follows (1) *intermittent insufficiency*, transient ischemic attacks, or incipient stroke; (2) *advancing stroke*, with stepwise development (with or without transient ischemic attacks—"stuttering"), transient ischemic attacks progressing to a persistent neurologic deficit, or a gradual slow onset with minor fluctuations, (3) *completed stroke* developing as a single abrupt event in minutes or hours, with or without stuttering fluctuations, in an advancing way as described above, or, as in some instances, a completed stroke with a fixed disability but followed by further transient ischemic attacks.

Steady progression of increasing neurologic signs and symptoms over a period of days or weeks without improvement usually indicates not a cerebrovascular attack but an expanding intracranial lesion There are some exceptions, however, as in gradual slow occlusion of ves-

lirium or coma, because of the cerebrovasoconstricting effect, with further diminution of cerebral blood flow (Table 15-12).

Chemoprophylaxis. Routine chemoprophylaxis of possible pulmonary or other infections is not recommended, principally because of the more serious risk of *superinfection*. The highest degree of success with *antibiotics* is obtained when they are used against specific organisms. A series of patients with respiratory distress who were *not* given routine antibiotics had a lower incidence of secondary infections than did those who *were* given routine antibiotics (Weinstein, 1955). Moreover, the types of organism in the treated group—such as *Pseudomonas*, penicillin-resistant *Staphylococcus*, and *Hemophilus influenzae*—were more difficult to combat. In addition to inducing the difficult superinfections, the routine administration of antibiotics predisposes to allergic episodes. It is concluded, therefore, that it is impossible to prevent infections completely, despite the use of potent antibiotic drugs alone or in combination. However, once an infection occurs, the actual condition should be treated with adequate doses of specific chemotherapeutic agents. The bacterial flora in the respiratory tract in patients with cerebrovascular attacks is usually mixed, and *broad-spectrum therapy* should be used.

Sedation. Many patients are restless, psychomotor behavior varies from the inactivity of *coma* or *stupor* to destructive hyperactivity in an *acute delirium*. Mild sedation by *phenobarbital* may be used but, in older patients, may cause more confusion or excitement. Difficulties in sleeping at night may be handled best with *chloral hydrate* or *paraldehyde*. *Tranquilizing drugs* of the phenothiazine group are useful, but their tendency to produce hypotension should be controlled. *Opiates should be avoided because of their depressant effect on respiration.*

Nutrition and Fluid Balance. Matters concerning the administration of fluids and food may be of extreme concern in the early phase of the illness. When the patient is in a stuporous or comatose state and unable to take any nourishment by *mouth*, *intravenous administration of fluids* becomes necessary. Occasionally, 5 per cent glucose solution in physiologic saline solution is indicated for *at least 1 to 2* liters, the remainder being 10 per cent glucose and distilled water. In some patients, *salt retention* develops, whether this has occurred should be determined by periodic estimations of serum sodium, especially when dehydration is present. Occasionally, if vomiting has been severe, *potassium deficiency* occurs. Other patients will have a significant *salt-wasting* syndrome (Welt et al., 1952) because of the secondary failure of the kidney to reabsorb salt in the proximal tubules and inappropriate antidiuretic hormone secretion. All these electrolyte alterations, particularly *hyponatremia*, may cause prolonged disturbances of consciousness and should be considered in patients who are not responding well to general therapy. In addition to electrolytes, proteins and calories are required by these patients. After the end of 1 week of ordinary intravenous salt and glucose therapy, it is usually necessary to supply up to 2000 cal per day and 0.5 to 1 Gm protein per kilogram of body weight. *Tube feeding is more efficient* than the administration of parenteral protein hydrolysate solutions. The tubes should be replaced periodically, every 24 to 48 hr. The disadvantages of leaving the tubes in place for prolonged periods are the production of increased nasopharyngeal secretions and the possibility of esophagitis.

Bladder Care. The care of the bladder is also extremely important in this acute stage. Incontinence of urine predisposes toward maceration of the skin and the occurrence of decubitus ulcers. In addition, a distended bladder may produce restlessness, otherwise not accounted for in a comatose patient. Although, in some instances, frequent changing of the bed sheets or proper urinal placement in the male may take care of the situation for 24 to 48 hr, it is usually more effective to catheterize the patient in order to prevent urinary retention and incontinence. The introduction of an indwelling catheter, however, causes bacterial invasion of the bladder and again raises the problem of *chemoprophylaxis*. However, even with routine administration of drugs, infections will occur in almost all patients. For the first 24 to 48 hr of using an indwelling catheter, open drainage is *satisfactory*; however, after this time, the catheter should be clamped off and released every 2 to 4 hr to prevent bladder contraction. It is highly recommended to use

is danger of herniation at the tentorium or foramen magnum following a *lumbar puncture*. Both *cerebral hemorrhage* and a *large infarct of the brain* may produce severe *edema* and *increase in intracranial pressure*. The findings upon lumbar puncture, however, are probably the best aid in differentiating between cerebral hemorrhage and infarction (Aring and Merritt, 1935). It should be remembered, however, that 10 to 15 per cent of patients with intracerebral hemorrhage do not have acute hemorrhage in the cerebrospinal spaces (hemorrhagic fluid), and that blood in the spinal fluid may be found in some patients with a hemorrhagic type of infarction, especially that due to *embolism*. Evaluation of *subarachnoid hemorrhage*, particularly in differentiation from meningeal infection, may require lumbar puncture Also, *cerebral neurosyphilis* may account for vascular attacks, and cerebrospinal fluid evaluation is necessary for positive diagnosis.

GENERAL CONSIDERATION OF TREATMENT

The present section is concerned with the general management of a patient with a moderate or severe cerebrovascular attack in the acute stage resulting in a disturbance of consciousness, altered respirations, and hemiplegia. Further details of diagnosis and special therapy will be given in the sections on specific types of attacks

The *immediate treatment* of a patient who has had cerebral vascular accident is devoted to maintaining life and restoring physiologic balance as best and as soon as possible The cornerstones of this treatment are based upon efficient *skillful nursing care* and *conservative expectant management* (Glaser, 1957). The patient should be placed flat in bed, and his position should be changed frequently, at least every 2 to 3 hr during the first 2 to 3 days It is extremely important during this time to prevent pulmonary complications and especially *hypostatic bronchopneumonia*

Respiratory Difficulties. Many patients have severe respiratory dysfunction in the acute stage, with stertorous breathing or *Cheyne-Stokes respiration*. *Suction* to remove nasal and oral secretions is extremely important, as is the maintenance of open airways An oral airway may be necessary; it is effected by holding the tongue and jaw forward. When choking, gagging aspirations, vomitus, or failure to cough secretions from the tracheobronchial tree interfere with breathing, the patient should lie on one side. Spontaneous coughing is easier in this position, drainage is better, and suction of the nasopharynx is more effective. The *aspiration of the nasopharynx* should be efficient, thorough, and frequent. Not only the mouth but also the posterior pharynx must be cleaned out A lubricated soft-rubber catheter should be used, and occasionally moved down far enough so that the epiglottis is touched. This may stimulate coughing and raise material from below the larynx If a major pulmonary blockage and atelectasis develop despite these measures, *bronchoscopy* should be performed In some patients, *tracheotomy* may be required The tracheotomy tube allows better suction and oxygenation.

Occasionally, *pulmonary edema* may occur, especially in patients with hypertension or coronary lesions and a tendency toward cardiac failure. This requires careful medical treatment with mercurial diuretics, parasympatholytics, digitalis, oxygen, and possibly defoaming agents.[1] *Morphine* is contraindicated, if sedation is necessary, *chloral hydrate* should be preferred. The patient with cardiac disease and orthopnea may have to remain in as convenient a sitting position as possible. This actually is not contraindicated in some patients who do not have cardiac disease and orthopnea, since the intracranial pressure is also lower in the upright posture. Many patients will require oxygen therapy following an acute cerebrovascular attack, for cyanosis often occurs as a result of inadequate breathing or cardiac failure. Either an *oxygen tent* or a *mask* is indicated Nasal catheters are not particularly recommended because they may be pulled out by the patient and, in addition, may cause necrosis of the posterior pharyngeal wall. The recommended rate of flow of oxygen is about 6 liters/min by mask and 8 to 10 liters/min in a tent in order to keep the oxygen concentration at about 45 or 50 per cent. There may be some value in adding 5 to 6 per cent *carbon dioxide* in order to produce cerebral vasodilatation, but this remains to be proved. It should be noted that oxygen concentrations of greater than 75 or 80 per cent may actually depress the arteriosclerotic patient and even cause *de-*

[1] For treatment of pulmonary edema, see also Part 18, Chap 14 *Editor.*

having had a cerebrovascular attack, and it is necessary to alleviate this fear in order to gain their maximum cooperation. This is especially true in patients having recurrent episodes.

TRANSIENT ISCHEMIC ATTACKS OR INTERMITTENT CEREBROVASCULAR INSUFFICIENCY

These attacks appear usually as recurrent warning episodes heralding the onset of a more severe cerebrovascular stroke (Brain, 1954, Corday et al, 1953, Denny-Brown, 1960, Fisher, 1958a, Rothenberg et al., 1957). They are ischemic in nature, because of alterations in local cerebral blood flow by mechanisms previously described, and are not seizures. Their main relationship is to cerebrovascular thrombosis or occlusion (*atherothrombosis*); they are, therefore, uncommon in the younger age group Most of these patients have hypertensive arteriosclerosis *Transient ischemic attacks are almost unknown prior to cerebral hemorrhage and are rare prior to a major embolic infarction.* It is important for these episodes to be diagnosed prior to the major infarction, appropriate prophylactic therapy is *anticoagulation* or *operative removal of a thrombus* followed by vascular reconstruction In cerebrovascular disease, therapy really must be preventive, treatment after a completed infarction usually has only moderate effects (Carter, 1957, 1960, Edwards et al, 1960; Fisher, 1958a, McDevitt et al, 1958; Millikan et al, 1958, Ushiro et al., 1957).

Diagnosis The signs and symptoms of transient ischemic cerebrovascular attacks usually indicate the nature of the impending infarction. Any cerebral artery, superficial or deep, may be involved, and recurrent episodes usually produce a similar pattern The attack may involve a major vessel or a minor one in strictly localized distribution The various clinical pictures are indicated in Table 15-13. In this type of attack, the brevity or transient nature of the episode is marked The duration varies from seconds to 1 hr, averaging 2 to 10 min, with no permanent residuals unless beginning infarction is taking place. The patient may experience a few attacks or hundreds, the outcome is unpredictable, as a completed infarction does not always occur The final result may be gradual, with progressively increasing neurologic deficit, or there may be a sudden precipitation The latter often occurs during sleep or shortly after the patient arises, probably because of related *hypotension*. However, often no drop of systemic pressure, directly correlated with the rapid development of symptoms, is demonstrable. Attacks also have been seemingly precipitated by exercise, emotional disturbance, heavy smoking, or bouts of coughing (Fisher, 1958a).

Transient ischemic attacks involve the vertebral-basilar vessels more often than the carotid system, and may be related to stenosing or obstructing lesions, even in the truncal vessels of supply, such as the subclavian or common carotid (Hutchinson and Yates, 1957; Meyer et al, 1960). Although vasospasm could account for these episodes, there does not appear to be any valid proof that it is a significant factor.

The differential diagnosis *should include* multiple recurrent embolism, epileptic seizures (*especially partial types*), migraine with "aura," Ménière's syndrome or primary labyrinthine disease *with vertigo, systemic hypotension* (Stokes-Adams, carotid sinus sensitivity), brain tumor, intermittent obstruction of the ventricular system, cyst of the third ventricle, small hemorrhages from basilar aneurysm, and various general symptoms appearing *in the elderly*, such as "dizziness" and akinetic *falling spells* Rare symptoms in transient ischemic cerebrovascular attacks are total loss of consciousness, major convulsive seizures, fecal and urinary incontinence, formed hallucinations, and manifestations of temporal lobe seizures.

Clear distinction should be made between *the transient* ischemic focal cerebrovascular attacks with local neurologic dysfunction, and *systemic hypotensive episodes* producing fainting or syncope with no localization of the ischemia A general hypotensive *crisis*, however, may contribute to the development of a localized cerebrovascular insufficiency, especially when there is a local vascular lesion, such as atheromatous narrowing of one of the vessels. These mechanisms have been reviewed above.

Another special *type of* ischemic episode is the "aura" of migraine, characterized by flickering scotomas, dysphasia, hemiparesis, *and* hemisensory syndromes. This [illegible]

[illegible] tree, but the mechanism is not known

tidal drainage if possible, since this definitely reduces the risk of infection.

Intracranial Pressure. Many patients have increased intracranial pressure, especially when cerebral hemorrhage is present This predisposes toward prolonged states of alteration of consciousness and, in addition, the possibility of brain herniation through the tentorium or foramen magnum. When the cerebrospinal fluid pressure is increased and the patient is comatose and dehydrated, the administration of fluids becomes difficult to adjust. In some instances the rapid intravenous administration of ordinary glucose and saline solutions will aggravate cerebral edema and raise the intracranial pressure further Lumbar puncture to reduce intracranial pressure is *not* recommended since it may cause brain herniation. Various other methods have been suggested to decrease elevated intracranial pressure but none of them is really satisfactory Intravenous administration of hypertonic sucrose or glucose solutions has been recommended. However, rebound pressure rises occur, and sucrose solution may be destructive to kidney epithelium. The use of *magnesium sulfate*, either intravenously or by proctoclysis, may be helpful, especially in hypertensive patients with severe cerebral edema. *Intravenous hypertonic urea solutions* should be administered only under careful control because of the possible development of hypernatremia and prerenal azotemia Generalized severe *headache* usually is related to increased intracranial pressure and responds to its control

Gastrointestinal Complications. Complications related to gastrointestinal tract disturbances occur in patients with acute cerebrovascular attacks. *Vomiting* may appear early and persist during the first 2 days The danger of aspiration of vomitus is great, and extensive and repeated vomiting may produce dehydration and disturbance of blood electrolytes Mild sedative therapy may be effective, as well as the use of small doses of tranquilizing drugs such as *chlorpromazine* and related substances The volume of fluid loss should be replaced if possible. If the patient continues to vomit in spite of attempts at control, the stomach should be kept empty by suction. Constant *hiccough* also may occur, especially in patients with vascular lesions of the medulla. Hiccough may be controlled by inhalations of 5 to 10 per cent *carbon dioxide* and occasionally by the administration of tranquilizing drugs, such as *chlorpromazine.* If these measures are not successful, *local anesthesia of the phrenic nerve* may be required. Rarely, some patients develop neurogenic ulcerations in the esophagus or stomach, which should be suspected if the vomitus contains blood or if the stools are tarry. Control of the patient's bowel function is also of importance in the acute phase Evacuation should be effected at least twice a week, enemas should be preferred to cathartics as they are less likely to involve soiling or severe straining

Convulsive Seizures. Occasionally, in the acute phase, convulsive seizures may occur, they are particularly frequent in patients with cerebral hemorrhage (Richardson and Dodge, 1954). A number of patients will have only one convulsion, but if recurrent seizures develop, *anticonvulsant medication* is indicated. Both *Dilantin sodium* and *phenobarbital* should be used, at first parenterally, if necessary, and then orally.

Hemiplegia. Most patients having a cerebrovascular accident develop varying degrees of hemiplegia. Usually, in the first days, the extremities are flaccid, but occasionally *spasticity* appears early within the first week The prevention of contractures is most important Correct bed positioning requires the use of a firm mattress or a board under the mattress A footboard or, better, a posterior leg molded plaster cast splint, is recommended to prevent foot drop and shortening or tightening of the Achilles tendon. Pillows are to be used under the shoulder and head to maintain good head position, and a small pillow should be placed in the axilla. To prevent contractures of the shoulder, knee, and hip, a sand bag or pillow should be placed lengthwise to relieve outward rotation at the hip, flexion at the knee, and adduction at the shoulder After the first 24 hr, the patient should have full, gentle, passive movements of all joints of the affected arm and leg, at least once or twice daily.

It is most important for the conscious patient to be reassured regarding his clinical condition This is particularly important for patients who have suffered a speech disturbance, particularly if they are still able to comprehend the spoken word However, even when the *aphasia* involves the auditory receptive functions, the patient can be reassured by the attitude of the physician. Most patients have a great fear of

particularly when there is suspicion of brain tumor or subdural hematoma *Angiography otherwise is best reserved for determining the extent and exact location of a stenotic or occlusive vascular lesion as a prelude to operative intervention* (Fig 15-40). There is increasing experience that arteriography in the older patients with hypertensive and atherosclerotic cerebrovascular disease is fraught with significant morbidity A carefully studied series recently reported had 22 per cent complications, including hemiparesis and aphasia (Baker, 1960).

Therapy. ANTICOAGULANT THERAPY. One of the major applications of anticoagulant therapy in the treatment of cerebrovascular attacks has been in these syndromes of intermittent cerebrovascular insufficiency or transient ischemic attacks involving the vertebral-basilar and internal carotid arterial trees (Fisher, 1958b, Groch et al, 1959, Millikan et al, 1955, 1958) The hope in these instances is to prevent further thrombotic occlusion of the involved vessel The patients selected for anticoagulant therapy should be nonhypertensive, although in some series the top level of blood pressure has been 200/100. Also, there should be no evidence of blood in the cerebrospinal fluid These criteria have been suggested in order to limit the possibility of cerebral hemorrhage. The evidence of the efficacy of this therapy is thus far uncertain In some series, there is distinct indication that recurrent attacks have been diminished significantly by the administration of anticoagulants and that further occlusion has been prevented (Fisher, 1958b, Millikan et al., 1955, 1958). There are many questions concerning the mechanism of action of anticoagulants in these instances, since it is felt that the anticoagulant effect as such may not be the only one (Denny-Brown, 1960, Meyer, 1958) There does not appear to be any direct interference with the process of atherosclerosis, but the anticoagulants may affect certain properties, such as blood viscosity. The anticoagulant therapy may improve the development of collateral circulation in some unknown way or limit minor embolization These may be factors, since changes in the frequency of ischemic attack may not occur for a few days.

The method of administration of the anticoagulants involves the careful use of *Dicumarol* (Fisher, 1958b, McDevitt et al, 1958, Millikan et al., 1958). Since this drug has a 24-hr latent period of action, the treatment during the first day is accomplished best by the use of *Tromexan ethyl acetate* or *heparin*, repeated to keep the venous clotting time elevated to about 20 min. The *clotting-time method* recommended is the Lee-White modification of the Howell method, which gives a normal clotting time of 5 to 8 min. Administration of Dicumarol is also started on the first day. Daily *prothrombin time tests* should be performed initially. The Link-Shapiro modification of the *Quick test*, which gives a normal time of 13 to 20 sec, is recommended. In effective anticoagulant therapy, the prothrombin time should be kept between 30 and 40 sec. The dosage of Dicumarol after the first day is adjusted according to the prothrombin time. If the prothrombin time goes above 60 sec or if hemorrhages occur, the Dicumarol should be discontinued and vitamin K should be administered It should be noted that during the first day, the prothrombin time should be determined prior to any dose of heparin, since large amounts of heparin in the blood may affect the prothrombin time value. It still has not been determined in any satisfactory fashion how long the anticoagulant medication should be administered The natural limitations of this form of therapy are great, because it requires frequent accurate determinations of prothrombin time, preferably every few days or at least once a week, and a very close long-term patient-physician relationship Often it is impractical to meet these requirements, particularly in a clinic population (Groch et al, 1959). It has been recommended that anticoagulant therapy might be used in hypertensive patients with numerous brief attacks or progressing thrombosis in addition to antihypertensive drugs. Blood pressures, for example, of 240/140 have been reduced to 180/100, at which level the use of anticoagulant therapy was regarded to be safe.

The effect of anticoagulant therapy has been variable in different series, but it is regarded by some to be particularly good in these patients with transient ischemic attacks. However, a significant number of distressing complications do occur, such as *intracerebral hemorrhage* (Barron and Ferguson, 1959) and *subarachnoid hemorrhage* and *epidural spinal hemorrhage* (Winer et al, 1959), in addition to *hemorrhagic disturbances* involving other regions of the body, such as the gastrointestinal tract and bladder (Groch et al, 1959). In a number of patients, the ischemic attacks continue, and thrombosis and occlusion develop despite anticoagulation therapy. These prob-

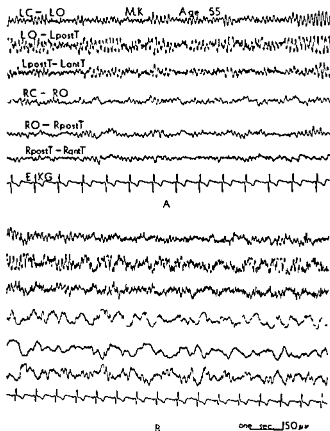

Fig. 15-39. Electroencephalograms of patient with occlusive lesion of right internal carotid artery and symptoms of right cerebral vascular insufficiency (see Fig 15-40 for arteriogram of same patient). A. Electroencephalogram in basal state Diffuse theta waves (5 to 7 cps) and disorganized, low-amplitude alpha activity from the right hemisphere, especially centrally. B. Electroencephalogram after tilting patient to 70° upright position for 5 min. Appearance of marked electroencephalographic abnormality from right hemisphere, 1 to 2 cps delta waves, especially centrally.

Certain diagnostic procedures are important in evaluating patients with transient ischemic cerebrovascular attacks *Ophthalmodynamometry* may demonstrate diminished pressure on the side of an insufficient carotid artery (Heyman et al, 1957) However, the results of this method have not been too consistent. While palpation of vascular pulsations in the neck usually is not a valuable test, pharyngeal palpation may be more effective At times decreased pulsations may be determined in the brachial vessels, indicating a general disturbance of circulation on that side Localized *bruit*, especially over the branches of the carotid artery, may be indicative of a significant partial blocking lesion (Crevasse and Logue, 1958). Compression of the carotid vessels in the neck as a testing procedure has been recommended (Gurdjian et al., 1960) but may be dangerous. Compression of an unaffected carotid vessel, for example, may result in symptoms, as the opposite vessel may be partially or totally occluded and the unaffected vessel may be the major source of supply to both hemispheres. This mechanism also may be responsible for bilateral symptoms in occasional cases of *unilateral carotid insufficiency* with both hemispheres competing for the remaining blood supply. These tests may induce convulsions or infarctions, while associated stimulation of the carotid sinus may also cause prolonged falls in blood pressure *Carotid compression tests* also have been found to be at least 20 per cent in error.

The *electroencephalogram* is usually normal in intermittent cerebrovascular insufficiency. At times, localized theta discharges may appear (Bruens et al, 1960). Occasionally, electroencephalographic recording during tilting to at least 70° may show the development of slow-wave changes over the temporal region on the side of a carotid insufficiency (Fig 15-39) and in one or both parieto-occipital regions in instances of basilar insufficiency (Meyer et al, 1956, 1957). A drop of 30 to 60 mm in systolic blood pressure usually is necessary, and the responses are found mostly in older individuals with hypertension In a number of patients, however, induced falls in blood pressure of at least 50 mm have not produced changes in the electroencephalogram or in symptoms (Weiss and Froelick, 1958).

Certain x-ray studies may be helpful An x-ray of the skull and the neck region may reveal calcification in vessels. X-rays of the cervical vertebrae may demonstrate anomalies or spondylosis which may relate to pressure syndromes involving the vertebral artery, especially associated with head turning The most significant radiologic method applied to the diagnosis of transient ischemic cerebrovascular attacks is angiography.

Because of the significant risks involved in this group, *cerebral angiography* is not to be regarded as a routine part of the medical management of patients with various types of cerebrovascular attacks (Millikan, 1960). Ideally, intrathoracic, cervical, and intracranial vessels should be visualized, but angiography to this extent often is not feasible. Occasionally, the procedure is worth performing for diagnosis

and great a fall in blood pressure may result in the production of actual cerebrovascular lesions. The rapid reduction of systemic blood pressure may produce further insufficiency in blood flow through already sclerotic and stenosed cerebral blood vessels.

Since many patients with transient ischemic [illegible]

(Nahum, 1960). Many of these patients have excessive weight, hypercholesterolemia, and hypertension. *Lipemia* may increase the tendency toward red cell aggregation in ischemic areas (Meyer et al., 1959). Other factors considered significant in this group are hypothyroidism, heavy smoking, and *diabetes*, as well as a definite family history of atherosclerosis. Reduction in blood pressure has been discussed above. In patients without significant permanent cerebrovascular lesions, the diastolic pressure should be maintained at levels of 90 mm Hg or less. Often limitation of sodium may not be accomplished merely by restriction of intake, and a drug such as *chlorothiazide* may be useful. In some patients, *aldosterone antagonists*, such as *spironolactone* (Aldactone), have been recommended. *Weight reduction* is recommended. Control of hypercholesterolemia and lipemia, which is difficult, may be attempted by the use of certain dietary restrictions (Katz et al., 1958, Nahum, 1960, Swank, 1959). This is particularly true if the cholesterol level of the serum is over 200 mg/100 ml. The diets recommended contain a minimum amount of animal and hydrogenated fats. In other diets, substitution of *vegetable oil* has been recommended. Other factors in atherogenesis that have been considered are hypothyroidism, diabetes, and estrogenic deficiencies. These disorders of hormonal imbalance should be treated by replacement therapy.

The relationship of *smoking* to atherogenesis is still not clear. There is evidence that smoking may increase the systolic blood pressure and contribute to general *hypoxia* by producing carboxyhemoglobin. There have been only the beginnings of an approach to drug therapy for atherosclerosis, and no studies have as yet been carried out in patients with transient ischemic cerebrovascular attacks. *Lipotropic agents*, such as choline, inositol, and essential fatty acids, do not lower plasma cholesterol or lipids significantly. Nicotinic acid is not recommended because of its generalized vasodilating effect. There is no evidence that pyridoxine deficiency is involved in the human disorder, but pyridoxine has been administered prophylactically. Ethylenediaminetetraacetate (calcium versenate) may lower the serum cholesterol concentration but is not effective in older patients. Newer substances which may interfere with cholesterol synthesis and be effective in human beings are awaited.

CEREBRAL INFARCTION OR ENCEPHALOMALACIA SECONDARY TO THROMBOTIC OR EMBOLIC OCCLUSION

Diagnosis. The great majority of patients with cerebral vascular accidents *who survive* the initial phase are victims of cerebral infarction or encephalomalacia secondary to thrombotic or embolic occlusion. As indicated above, the infarction may be due to *thrombotic occlusion*, *embolization*, or *progressive severe insufficiency*. Carotid artery tree involvement is suggested by unilateral extremity paralysis of a *motor or sensory nature*, associated with dysphasia and unilateral loss of vision or hemianopsia. Lesions of the basilar artery and derived branches are indicated when there are *bilateral* extremity and cranial nerve signs along with cerebellar dysfunction, bilateral disturbances in the visual fields, and alterations of *consciousness*. The various syndromes involving specific blood vessels are indicated in Table 15-13. Infarction is often preceded, as described above, by episodes of transient cerebral vascular ischemia or intermittent insufficiency, this type of progression has been described as *"stuttering,"* with increasing stepwise neurologic deficits. Occasionally, there is a sudden onset of *infarction* with a complete lesion occurring in a short period of time and producing a complete hemiplegia and severe aphasia.

The onset of *embolic occlusion* is usually sudden. Embolization may be from various sources, and the frequency of embolic occlusion is regarded to be higher than previously realized. The embolus may originate from mural thrombi in myocardial infarction, auricular thrombi in patients with fibrillation, vegetations from the valves in septic or aseptic endocarditis, atheromatous plaques and associated thrombi in the large arteries of the neck, and as fat emboli from fractures.

Fig. 15-40. Occlusive lesion (atherosclerotic) of cervical portion of right internal carotid artery, demonstrated by carotid angiography. A bruit was heard over the right carotid vessel in the neck at jaw level.

lems may limit the application of this therapy Continued detailed evaluation of this form of treatment certainly remains indicated

OPERATIVE PROCEDURES ON INVOLVED ARTERIES. In appropriately selected patients, various operative procedures have been performed in order to relieve localized stenotic and occlusive lesions (Crawford et al, 1959, Edwards et al, 1960). The specific diagnosis is made by angiography, and the patients selected are those with a history of intermittent cerebrovascular insufficiency with few if any significant neurologic residuals (Fig 15-40) The operative procedures are *thromboendarterectomy, bypassing grafts*, and various other reconstructive procedures. Lesions in the cervical portions of the carotid and vertebral vessels have been most accessible by these techniques, and the use of *hypothermia* during operation has limited the morbidity. Results have been variable but are best with lesions producing incomplete stenosis and partial occlusion. In a number of instances, anticoagulant therapy is recommended after operation in order to prevent further thrombosis of the reconstructed artery. The utilization of these operative procedures awaits further analysis and more general information concerning the interval between atherosclerotic segmental carotid stenosis and attacks of insufficiency. Such lesions are common in the vessels of persons over 50 years of age, many of whom have had no history of symptoms or signs of cerebrovascular attacks (Millikan, 1960). At present, it seems that the patients best suited for surgery are those with transient ischemic attacks without neurologic deficits and with demonstrable, unilateral, localized, incomplete lesions involving the lower portion of the internal carotid near its origin or the vertebral near its origin, both being extracranial locations Postoperative recurrence of symptoms does occur, and long-term follow-up studies are necessary.

FURTHER CONSIDERATIONS OF MEDICAL MANAGEMENT. Aside from decisions concerning the use of anticoagulation therapy and operative procedures, attention must be paid to other aspects of medical management in these patients with transient ischemic attacks. Many patients may not receive anticoagulation therapy because of the degree of hypertension or for other reasons, and the surgical approach is limited to only a small number of carefully selected patients. *Adequate treatment should include measures designed to control blood pressure, particularly low levels and hemodynamic crises* (Denny-Brown, 1960). Maintenance of an adequate degree of head pressure may be necessary to overcome the peripheral resistance of the small vessel bed This may prevent the development of neurologic signs (Shanbrom and Levy, 1957). Episodes of anemia, myocardial infarction, or gastrointestinal bleeding should receive primary attention. Many patients cannot receive anticoagulation therapy for a lifetime, and in them these other controls are of major importance. The evaluation of compressing syndromes of the vertebral vascular system, due to involvement of the cervical vertebrae, may lead to a more appropriate therapeutic approach, such as wearing a neck collar

Many patients with intermittent cerebrovascular attacks are hypertensive. The hypertension should be carefully controlled by weight reduction, administration of sedative drugs, and the use of *Rauwolfia* or its derivatives Additional help may be obtained from *low-sodium diets* and the *antihypertensive drugs*, which act as autonomic blocking agents These should be used with great care in patients with cerebrovascular attacks, since too precipitous

and great a fall in blood pressure may result in the production of actual cerebrovascular lesions The rapid reduction of systemic blood pressure may produce further insufficiency in blood flow through already sclerotic and stenosed cerebral blood vessels.

Since many patients with transient ischemic cerebrovascular attacks have atherosclerotic lesions (Baker and Iannone, 1959), attempts should be made to control this disease process (Nahum, 1960). Many of these patients have excessive weight, hypercholesterolemia, and hypertension *Lipemia* may increase the tendency toward red cell *aggregation in ischemic* areas (Meyer et al, 1959). Other factors considered significant in this group are *hypothyroidism, heavy smoking,* and *diabetes*, as well as a definite family history of atherosclerosis Reduction *in* blood pressure has been discussed above. In patients without significant permanent cerebrovascular lesions, the diastolic pressure should be maintained at levels of 90 mm Hg or less Often limitation of sodium may not be accomplished merely by restriction of intake, and a drug *such as chlorothiazide may be useful*. In some patients, *aldosterone antagonists, such as spironolactone* (Aldactone), have been recommended. Weight reduction is recommended Control of hypercholesterolemia and lipemia, which *is difficult*, may be attempted by the use of certain dietary restrictions (Katz et al, 1958, *Nahum, 1960*, Swank, 1959). This is particularly true if the cholesterol level *of the* serum is over 200 mg/100 ml The diets recommended contain a minimum amount of animal and hydrogenated fats In other diets, substitution of vegetable oil has been recommended *Other factors* in atherogenesis that have been *considered* are hypothyroidism, diabetes, and estrogenic deficiencies These *disorders* of hormonal imbalance should be treated by replacement therapy.

The [illegible] is still [illegible] ing ma[illegible] blood pressure and contribute to general *hypoxia* by producing carboxyhemoglobin There have been only the beginnings *of an* approach to drug therapy for atherosclerosis, and no studies have as yet been carried *out* in patients with *transient* ischemic cerebrovascular attacks. *Lipotropic agents*, such as choline, inositol, and essential fatty acids, do not lower *plasma* cholesterol or lipids significantly. Nicotinic acid is not recommended because of its generalized vasodilating effect. There is no evidence that pyridoxine deficiency is involved in the human disorder, but pyridoxine has been administered prophylactically. Ethylenediaminetetraacetate (calcium versenate) may lower the serum cholesterol concentration but is not effective in older patients. Newer substances which may interfere with cholesterol synthesis and be effective in human beings are awaited

CEREBRAL INFARCTION OR ENCEPHALOMALACIA SECONDARY TO THROMBOTIC OR EMBOLIC OCCLUSION

Diagnosis. The great majority of patients with cerebral vascular accidents who survive the initial phase are victims of cerebral infarction or encephalomalacia secondary to thrombotic or embolic occlusion. As indicated above, the infarction may be due to *thrombotic occlusion*, embolization, or *progressive severe insufficiency* Carotid artery *tree involvement is suggested by unilateral extremity* paralysis of a motor or sensory nature, associated with dysphasia and unilateral loss of vision or hemianopsia. Lesions of the basilar artery and derived *branches are* indicated when there are *bilateral* extremity and cranial nerve signs *along* with cerebellar dysfunction, bilateral disturbances in the visual fields, and alterations of consciousness The various syndromes involving specific blood vessels *are indicated in* Table 15-13. Infarction is often preceded, as described above, by episodes of transient cerebral vascular ischemia or intermittent insufficiency; this type of progression has been described as *"stuttering,"* with *increasing* stepwise neurologic *deficits*. Occasionally, there is a sudden onset of *infarction* with a complete lesion *occurring in a short* period of time and producing a *complete* hemiplegia *and* severe aphasia

The onset of *embolic occlusion* is usually sudden. Embolization *may be* from various sources, and the frequency of embolic occlusion is *regarded* to be higher than previously realized The embolus may originate from mural thrombi in myocardial infarction, auricular thrombi in patients with fibrillation, vegetations from the valves in septic or aseptic endocarditis, atheromatous plaques and associated thrombi in the large arteries of the neck, and as fat emboli from fractures

Coma, convulsions, and *headache* occur in about 30 per cent of patients with these lesions. There may be elevated temperature and increased pulse rate, along with abnormalities of respiration, particularly of the *Cheyne-Stokes* type. Cerebral thrombosis or embolism may occur in the presence of normal blood pressure, but hypertension more commonly is present in patients with thrombotic occlusion. Signs of sensorial difficulty, such as confusion, disorientation, and impaired memory, are frequent after a cerebrovascular attack. In the early phase, associated with *stupor* or *coma,* the deep tendon reflexes may be hypoactive in the involved hemiplegic extremity, and, within the first 24 hr, a bilaterally positive *Babinski's sign* may be present, appearing later in the paralyzed extremity only. Other general signs may include *albuminuria,* especially in hypertensive patients, transient *hyperglycemia* and *glycosuria,* even in the absence of diabetes, and a slight peripheral *leucocytosis.* The cerebrospinal fluid pressure is usually normal in patients with cerebral embolism or thrombosis, although, rarely, pressures above 200 mm do occur Fifteen per cent of patients with cerebral embolism may have *blood in the cerebrospinal fluid* This is rare in patients with cerebral thrombosis, although there may be a slight *xanthochromia* The cerebrospinal fluid protein may be slightly elevated, but values above 100 mg are unusual The serologic reactions are negative unless the cerebrovascular lesion is due to syphilitic disease There may be a slight elevation in the number of white cells in the cerebrospinal fluid, up to 50, and higher levels may be related to septic embolization

The *electroencephalogram* may show a slow-wave focus in the involved hemisphere, usually with high-amplitude slow waves, in frequency ranges between 3 and 4 cps with severe lesions and 5 to 7 cps in the less severe (Bruens et al., 1960). Rarely, electrical activity from the involved hemisphere may be suppressed In patients with seizures or a developing seizure potentiality, sharp waves and spikes may appear from the focally abnormal regions These electroencephalographic abnormalities in cerebrovascular lesions tend to fluctuate and eventually regress toward normal *X-ray studies* of the skull usually do not show any significant abnormalities. However, they are useful to obtain when there are questions in differential diagnosis, particularly in relation to brain tumor or subdural hematoma.

The fixed cerebrovascular lesion, infarction, produced by thrombotic occlusion or embolization, must be differentiated from expanding intracranial lesions such as brain tumor, abscess, and subdural hematoma or metabolic disorders such as uremia, diabetic acidosis, and drug intoxication. The differential diagnosis is aided by a careful history and examination of the patient, as well as by studies such as urine examination, determination of blood sugar and nonprotein nitrogen, cerebrospinal fluid examination, skull x-rays, electroencephalography, and possibly pneumoencephalography, ventriculography, and angiography.

A diabetic complication is usually ascertained by the examination of blood sugar and electrolytes. The hyperglycemia of diabetes usually is much greater than the slight rises appearing with cerebrovascular attacks Uremia may merely be part of the general picture of associated chronic renal disease with hypertension and a cerebrovascular accident, but may account for many of the symptoms.

Chronic alcoholic patients may present a picture resembling a cerebrovascular attack when they are in a state of *acute alcoholic intoxication.* However, these patients, too, may have suffered a cerebrovascular accident or may have a subdural hematoma or extradural hematoma The differential diagnosis between cerebral infarction and subdural hematoma is extremely important because of the significantly good response to operation of subdural hematoma There may not be a clear history of head injury, or there may be an interval of many weeks between a relatively minor head injury and the onset of neurologic symptoms. *Subdural hematoma* should be suspected when there are fluctuations in the patient's state of consciousness, and when there is a progressive worsening in the neurologic signs and symptoms, such as increasing hemiplegia and aphasia Cerebrospinal fluid findings in subdural hematoma may be increased pressure, xanthochromia and elevated protein, and the presence of erythrocytes X-ray of the skull may reveal displacement of a calcified pineal gland There may not be significant signs or symptoms of increased intracranial pressure The electroencephalogram may be of help by revealing suppression or flattening of electrical activity over the involved hemisphere This

does not occur in all cases of subdural hematoma, and occasionally a slow-wave focus may be found If the diagnosis is seriously suspected but otherwise not confirmed, it is worthwhile to consider performing an angiogram, a bilateral trephine opening in the skull, or both. The clinical picture of brain tumor or brain abscess usually differentiates these illnesses from cerebrovascular attacks The onset is slower, and there is a more gradual, progressive development of symptoms and signs. Significant increases in intracranial pressure, papilledema, usually normal blood pressure, and increase in protein content of the cerebrospinal fluid above 100 mg/100 ml are major findings. Cerebrospinal fluid transaminase is usually not elevated in brain tumors, but may be elevated following cerebral infarction (Katzman et al., 1957). With a brain abscess, the cerebrospinal fluid may show a pleocytosis, but exceptions do occur. The electroencephalogram in these expanding intracranial lesions shows a progressively increasing enlargement of a slow-wave focus Seizures, both focal and generalized, are more common in patients with irritating expanding intracranial lesions, but they occur also in cerebrovascular accidents

The clinical course of patients with cerebral infarction is usually one of progressive improvement but with residual neurologic deficits, such as hemiplegia, hemisensory loss, dysphasia, and often some disturbance in mental functioning. Recurrences are possible, although the time interval between them may be extremely variable

In elderly patients, particularly those with hypertension and severe arteriosclerosis, small thrombotic lesions may occur repeatedly, producing multiple lacunar infarctions throughout the brain, particularly in the central white matter of the temporal and parietal lobes and the basal ganglia. There may be no severe initial dysfunction, such as hemiplegia, but progressive weakness and spasticity may develop gradually in all four extremities, along with gradual demential and pseudobulbar palsy

Cerebrovascular attacks with infarction occasionally appear in certain small-vessel diseases Thromboangiitis obliterans, or Buerger's disease, may show these complications in a small percentage (about 1 per cent) of patients (Fisher, 1957, Lippmann, 1952, Llavero, 1948). The lesions may involve the larger blood vessels, with carotid artery thrombosis, but more often, they involve the branches of these vessels, especially of the middle cerebral. The neurologic signs and symptoms are varied and usually transient before becoming permanent.

Diffuse and focal lesions of the central nervous system occur in collagen diseases, especially periarteritis nodosa and acute systemic lupus erythematosus, producing a myriad of clinical pictures with focal and generalized convulsions, dysphasia, paralyses, electroencephalographic changes, and organic mental deficits (Glaser, 1955). The cerebral lesions are secondary to proliferative and degenerative changes in the connective tissue of the smaller blood vessels leading to occlusion or rupture, with resultant disseminated ischemic changes or multiple small cerebral infarctions (Glaser, 1952).

Therapy. The general management of the patient in the acute stage following a cerebral infarction has been discussed above. Many physicians treating patients with cerebrovascular attacks become discontented with expectant conservative therapy, bed rest, and nursing care In the hope of decreasing neurologic residuals and preventing further attacks, more active treatments and procedures have been developed: vasodilating drugs, stellate ganglion block, cortisone, anticoagulant therapy, operative intervention, and the use of lysing enzymes. It may be stated at the outset that these treatments are of little or no benefit in infarction secondary to thrombotic occlusion but some of them may be helpful in the management of cerebral embolization.

VASODILATING DRUGS These drugs have been recommended in the treatment of cerebral infarction due to thrombosis, embolism, or insufficiency of circulation It has been stated already that the use of drugs which produce a generalized vasodilatation in systemic hypotension may not be effective in treating cerebrovascular disease because of the production of further cerebrovascular insufficiency due to the predominant effect of these drugs on the splanchnic vessels, causing a secondary decrease of blood flow through the brain. This result may be more disturbing than any possible direct effect of cerebral vasodilatation. Actually, the tissue metabolites in the damaged area, such as carbon dioxide, already may have produced maximal dilatation

The various drugs that have been recommended include *papaverine, histamine, Priscoline, nicotinic acid,* and *alcohol.* As may be seen in Table 15-12, the direct effects on general cerebral blood flow are not particularly significant. *Aminophylline* is not a vasodilator and may further impair cerebral circulation in patients with cardiac failure. In cerebral embolization, however, papaverine hydrochloride has been strongly recommended to control "vasospasm" in the collateral areas (Russek and Zohman, 1948). Results with this drug often are not remarkable, and there is still a need for more adequately controlled studies. *Carbon dioxide* in concentrations of 5 to 6 per cent is a most potent cerebrovasodilator, but there has been no carefully controlled investigation indicating any significant effect on the general state of the patient or on the residual neurologic deficit.

STELLATE GANGLION BLOCK The use of cervical sympathetic block has been recommended for the treatment of cerebrovascular attacks, particularly those of cerebral infarction due to thrombosis or embolic occlusion, whether the infarction be anemic or hemorrhagic (de Takats, 1954). In order for it to be effective, it has been recommended that a bilateral stellate ganglion block be performed *during the first 24 hr.* However, it has been demonstrated that this procedure does not significantly affect the cerebral blood flow in normal or hypertensive patients (Table 15-12), controlled clinical reports have shown that this procedure is not effective and does not change the chance variation of the clinical situation or the spontaneous occurrence of improvement (Millikan et al, 1953). There is the probability, already noted, that cerebral vasospasm is not a significant mechanism in the pathogenesis of these lesions

CORTISONE. Cortisone has been administered in the treatment of cerebral infarction in the hope that it would retard the development of cerebral edema, limit the tendency to herniation of large infarcts, and reduce mesenchymal tissue response to the trauma of the vascular accident (Russek et al, 1955) The steroids have been administered to patients with hypertension and diabetes without any significant complications. However, the results produced have been difficult to evaluate (Dyken and White, 1956); in general, it was regarded that the dangers of administering steroids probably outweigh any improvement that they might effect. They are not recommended as a safe means of therapy in the early stages of the usual cerebrovascular accidents. Adrenal steroids are useful in the management of these lesions in the collagen diseases (Glaser, 1955).

ANTICOAGULANT DRUGS. There is general agreement that anticoagulant therapy has no significant effect upon a completed infarction produced either by progressive severe insufficiency, with or without thrombotic occlusion, or by cerebral embolization (Carter, 1957, 1960, Fisher, 1958b; McDevitt et al, 1958, Millikan et al., 1958; Ushiro et al, 1957) However, this therapy has been recommended for the prevention of further embolization (Carter, 1957, McDevitt et al., 1958, Ushiro and Schaller, 1957; Wells, 1959). The criteria for selecting patients for anticoagulation therapy after cerebral embolization are the same as discussed above with regard to the transient ischemic attacks, and the method of administration of the anticoagulant therapy is similar There are some as yet unsolved questions concerning the timing of the beginning of anticoagulant therapy after a cerebral embolization. Experimental studies have shown that in animals with experimental embolic infarction the use of anticoagulation therapy increases the hemorrhagic nature of the infarction (Peterman et al., 1959, Sibley et al., 1957, Whisnant, 1959, Wood, 1958). Since the infarction of cerebral embolization is regarded to be a type of hemorrhagic infarction, there is the risk of increasing the already existing bleeding. It is recommended, therefore, that the anticoagulation therapy be started at least several days after the embolization in order to limit, if possible, the danger of further hemorrhage into the infarction *There appears to be adequate statistical data indicating that anticoagulation therapy prevents recurrent cerebral embolization* (*McDevitt et al*, 1958). The recurrence rate has dropped about eightfold However, there is the risk of hemorrhagic complication in the brain, as well as elsewhere in the body (see above). Cerebral hemorrhage into even an old infarction has been a significant cause of death in patients so treated (Fig. 15-41). Yet the supporters of this form of therapy feel that although this risk of hemorrhage is present, it is not excessive considering the over-all results in a large group of patients (Carter, 1957; Groch et al, 1959, McDevitt et al, 1958).

OPERATIVE INTERVENTION. Once a cerebral infarction has occurred, there are no indications that operative intervention is of benefit The responses to *thromboendarterectomy* are best, as discussed above, in patients with partial stenosing lesions and in those without completed infarction and with mainly a syndrome of transient cerebrovascular attacks (Crawford et al, 1959, Edwards et al., 1960, Millikan, 1960)

THE USE OF LYSING ENZYMES There have been a few attempts to determine the effect of lysing enzymes such as *plasmin or fibrinolysin* on thrombotic lesions (Clifton, 1958, Moser, 1959, Sherry et al., 1959), but thus far there have been no significant results pertaining to the treatment of cerebrovascular thrombosis Further studies are warranted, however.

INTRACEREBRAL HEMORRHAGE

Diagnosis. Massive intracerebral hemorrhage usually occurs in patients with systemic hypertension, but it may be caused by a ruptured aneurysm, cerebral angioma, embolization in subacute bacterial endocarditis, and the various hemorrhagic blood dyscrasias The mortality rate within the first 24 to 48 hr may reach at least [illegible]

[illegible]

bone or embolic occlusion, as described above, and is limited to an area of specific blood supply Severe hemorrhage, however, may occur in an area of infarction Intracerebral hemorrhage usually involves the cerebral hemispheres, less often, it affects the cerebellum and brain stem The onset is usually sudden but may be gradual, in most instances, the severity and intensity of the disorder reach a peak within minutes or a few hours at most Death often occurs within 2 hr Tentorial herniation is common, contributing to severe brain stem dysfunction and causing bilateral signs Hemorrhage into the cerebral hemispheres is often of sudden onset, with convulsions, severe headache, nausea, vomiting, and coma (Aring and Merritt, 1935) Hemorrhage into the brain stem, particularly the pons, has a severe onset with coma and collapse, bilateral pupillary dysfunction producing marked constriction, and extraocular palsies Respiratory difficulty, with *Cheyne-Stokes breathing*, is common Cerebrospinal fluid is uniformly bloody and under increased pressure.

Fig 15-41. Hemorrhagic infarction and intracerebral hemorrhage in region of supply of middle cerebral artery.

Treatment. Because of the high fatality rate, and since the diagnosis usually can be made with certainty in most cases, any reasonable treatment has been worth a trial Usually, only the medical management of the seriously ill and comatose patient can be offered. *There is no effective method of stopping an acute brain hemorrhage Hypothermia* has been considered but has not been used as yet in any controlled way. *Operative removal* of an intracerebral hematoma has been considered in many patients who have survived the initial shock of a cerebral hemorrhage (Davidoff, 1958). *In some instances, this procedure has proved to be lifesaving and of benefit in limiting residual neurologic deficits* However, the usually prolonged coma and the poor general state of the patient are deterrents to frequent use of operative treatment. There is some agreement now that the clinical picture most favorable to surgery consists of the sudden onset of signs and symptoms of hemorrhage in a patient who has not lost consciousness or in whom consciousness has completely returned, survival for a few days even with stupor or light coma, and then the development of progressive signs of increased intracranial pressure, such as a deepening of stupor or coma and papilledema. The surgical procedure performed in this subacute stage is either *burr hole drainage* or *evacuation of hematoma* through a *craniectomy* opening The reported operative mortality rate has ranged from 12 to 28 per cent, which is relatively low considering the high degree of mortality of the initial condition However, cases suitable for this treatment are unusual

HYPERTENSIVE ENCEPHALOPATHY

Diagnosis. Hypertensive encephalopathy is a specific acute or subacute disorder of the nervous system in patients with severe hypertensive cardiovascular disease. It is manifested by rapid elevation in blood pressure to higher levels than usual for the patient and by the occurrence of severe headaches, focal and generalized convulsions, papilledema, blindness, mental confusion, transient focal neurologic signs and symptoms, such as hemiplegia and aphasia, and the appearance eventually of stuporous or comatose states. It is usually associated with a crisis of severe elevation of blood pressure and absence of marked uremia. Massive intracerebral hemorrhage may occur eventually in severe cases Repeated episodes may produce widespread residual neurologic deficits

Hypertensive encephalopathy occurs in chronic hypertensive disease, especially associated with nephritis, as well as in acute eclampsia, acute nephritis, and some of the acute collagen diseases, such as periarteritis nodosa and lupus erythematosus.

The pathogenesis of this condition is still not clear. Necrotic arterial lesions exist in the brain, and cerebral edema occurs, with focal areas of ischemia (Pickering, 1948) It is still questionable whether focal cerebral vasospasm occurs (Byrom, 1954). However, focal small hemorrhages and occlusions are thought to be responsible

Treatment. The treatment of patients with hypertensive encephalopathy includes bed rest, lowering of the increased blood pressure, prevention of heart failure, reduction of cerebral edema and increased intracranial pressure, and the control of convulsions The withdrawal of up to 500 ml blood as an emergency measure may be effective, particularly when *pulmonary edema* is present. *Lumbar puncture* is not recommended because of the presence of cerebral edema and the danger of brain herniation *Magnesium sulfate* may be administered, intravenously or rectally, as a depressing agent The use of antihypertensive drugs has been recommended to control acute hypertensive crisis The actual dosage levels of these drugs, particularly the *autonomic blocking agents*. have to be adjusted to the individual patient and his blood pressure. Much care should be taken not to induce too precipitous a fall in blood pressure, as this may result in the production of a new cerebrovascular lesion, i e, an infarct secondary to further ischemic or anoxic encephalopathy. In some instances, where the hypertensive encephalopathy is of relatively moderate degree, effective results may be attained by *bed rest* and the use of an effective sedative, such as *phenobarbital,* which is also anticonvulsant.

SUBARACHNOID HEMORRHAGE

The primary subarachnoid hemorrhages are believed to be caused mainly by rupture of a *congenital arterial aneurysm of the circle of Willis* or by an *arteriovenous angioma* (Walton, 1956). So-called secondary subarachnoid hemorrhages are caused by *head trauma*, hemorrhagic blood dyscrasias, bleeding intracranial tumors, septic emboli, other infectious disorders of the nervous system, or intracerebral hemorrhage with leakage into the subarachnoid space. Generally, the spontaneous primary subarachnoid hemorrhages occur in a younger age group, about half appearing before the age of 40 years. Systemic hypertension and arteriosclerosis occur commonly in the middle-aged or older patients with subarachnoid hemorrhage and are contributing factors Cerebral aneurysms are common in patients with coarctation of the aorta and with polycystic disease of the kidneys.

The congenital or *berry aneurysms* usually are due to congenital weakness of the vascular wall, particularly the media, and especially at the points of bifurcation. They commonly appear at or near the circle of Willis, and vary in size up to large saccular masses, then producing symptoms by compression of the brain substance or cranial nerves. Up to 50 per cent of these aneurysms appear on either the internal carotid or middle cerebral arteries, about 25 per cent involve the anterior communicating or anterior cerebral, and about 15 per cent the basilar and its branches (McDonald and Korb, 1939, Richardson and Hyland, 1941). Rarely, aneurysms of intracranial arteries are dissecting (Scott et al., 1960).

Diagnosis. The onset of a subarachnoid hemorrhage is usually sudden, with a severe attack, characterized by excruciating *headache,* particularly involving the occipital region; collapse, signs of meningeal irritation; and the appearance of grossly *bloody cerebrospinal fluid* under increased pressure. Loss of con-

sciousness may occur quickly. Many patients develop a severe state of confusion and delirium The onset may follow exertion, but does not always do so There are usually no significant localizing signs. Hemorrhage into or irritation over the surface of the cerebral hemispheres may produce *focal seizures* or signs of localized motor or sensory dysfunction Many of the aneurysms are located near the oculomotor nerve and may produce a *third nerve palsy* In some instances, prior to the actual major subarachnoid hemorrhage, patients experience chronic or periodic *unilateral headaches*, similar to migraine and occasionally associated with diplopia and involvement of the oculomotor nerve At times, the sella turcica is eroded by a large aneurysm and symptoms of pituitary insufficiency are present Pressure on the optic nerve, chiasm, or optic tract may produce characteristic visual field deficits. In rare instances, temporal lobe seizures may occur, secondary to compression of the middle cerebral artery by a large aneurysm Seizures may be due to angioma

The signs of meningeal irritation usually are severe, with markedly stiff neck and positive *Kernig's* and *Brudzinski's signs*. Some patients complain of severe pain radiating down the lower back and legs, presumably because of blood in the lumbar subarachnoid space. Hemorrhages may appear in the retina, usually in a subhyaloid location, and slight degrees of papilledema may be present

Body temperature is moderately elevated, occasionally up to 102°F, and blood pressure is elevated This may be a result of the subarachnoid hemorrhage and not associated with previous history of hypertension A slight peripheral *leucocytosis* is common *Albuminuria* and *elevation of blood non-protein nitrogen* may occur. *Hyperglycemia* and *glycosuria* also may appear The cerebrospinal fluid pressure is often in marked elevation, to over 500 mm fluid The fluid has a uniformly bloody appearance, and there is an elevation in cerebrospinal fluid protein The number of white cells in the cerebrospinal fluid may be somewhat higher than expected from the amount of blood because of reaction to the blood Cerebrospinal fluid sugar usually is within the normal range These changes in the cerebrospinal fluid usually differentiate subarachnoid hemorrhage from acute bacterial meningitis, which may produce the same type of symptoms and signs

The natural history of the development and course of symptoms in recovery in this illness is still not completely worked out (Magladery, 1955, McKissock and Paine, 1959, Walton, 1956). The initial mortality ranges between 35 and 50 per cent, with the highest rate occurring during the first few days (over 25 per cent). Later, recurrent bleeding occurs in 20 per cent of the patients, usually within the second and third weeks, with a second 50 per cent mortality at this time. However, 60 to 90 per cent of the patients surviving the first few weeks may recover Certain factors related to recurrence are age, hypertension, and arteriosclerosis. The mortality in normotensive patients under the age of 60 is around 30 per cent, in contrast to about 50 per cent for the general group The development of neurologic deficits, such as hemiplegia and aphasia, may be related to direct effects of bleeding However, vasospasm of the vessel of origin in the aneurysm may be a responsible factor.

Treatment. The major problem in therapy of subarachnoid hemorrhage is the decision between conservative medical management and operative treatment (Magladery, 1955, McKissock and Paine, 1959, Walton, 1956). Further questions concerning the surgical approach relate to arteriography. Well-controlled comparative studies between the different forms of therapy still are not yet available. *Surgical intervention* has reduced the mortality rate in certain types of aneurysm (Botterell et al, 1958). Probably the best way to analyze this condition is to regard aneurysms of different locations as essentially separate entities In the over-all group of patients with subarachnoid hemorrhage, however, those with these selected operable aneurysms still represent a small number, and it is still not known whether an ultimate mortality rate is significantly decreased by surgical intervention (Magladery, 1955, McKissock and Paine, 1959).

There are two danger periods in relation to mortality and recurrence during the acute phase of ...

... during this period. However, it has been recommended by some groups, and with newer, more careful techniques, the risks may be limited (Pool et al, 1959). In general, the procedure is most effective if performed between the fifth and tenth days. Yet, even though it may be assumed that a congenital aneurysm is present in up to

75 per cent of patients as the cause of subarachnoid hemorrhage, arteriography, as usually performed, is positive in only 50 per cent of the group. It should be realized, in addition, that, since some patients have no localizing neurologic signs, *it may be necessary to perform three arteriograms, two carotid and one vertebral, in order to demonstrate the aneurysm.* In some instances, actually in increasing number, *multiple aneurysms* will be found bilaterally. It may be possible, by careful neurologic evaluation, to determine which of these aneurysms is responsible for bleeding. However, this usually is not so. In the past, the risks of arteriography in this group have been regarded as significant, with up to 1 per cent mortality rate, in addition to permanent complications, such as hemiplegia and dysphasia, in another 1 per cent or transient symptoms in 2 per cent of the patients. These risks have been reduced by improved techniques (Sedzimir, 1955). However, the complications still remain frequent in older patients with arteriosclerosis and hypertension up to 22 per cent (Baker, 1960). Arteriography should be performed only if surgical intervention is to be considered, or when it is absolutely required for diagnosis.

Conservative medical management is indicated when the origin of the subarachnoid hemorrhage is not a bleeding vascular anomaly or when a suspected aneurysm cannot be located arteriographically and characteristic regional neurologic signs are absent. In addition, medical therapy must be continued when (1) arteriography demonstrates an aneurysm on an indispensable or inaccessible major artery, such as the middle cerebral or basilar, and is not operable, (2) multiple aneurysms are present bilaterally, and (3) collateral circulation is inadequate through the circle of Willis as determined by preliminary carotid compression. The basis of conservative medical management is maximal strict *bed rest* in the acute stage, with rigid attention to control of breathing and adequate aeration, control of electrolyte balance, and avoidance of all forms of strain. Bed rest should be continued for at least 4 to 6 weeks after the acute bleeding stage. Many patients have systemic hypertension, and antihypertensive drugs have been recommended. While small reductions in blood pressure may be helpful, sudden drops are to be avoided. During the first few days, the symptoms of severe headache, anxiety, tension, and restlessness may require control by drugs. *Sedation* with *barbiturates* is helpful, in addition to the administration of mild *analgesics*, such as *aspirin*. If headache is severe, small doses of *codeine* or similar drugs may be administered. However, narcotics generally should be avoided because of the dangers of respiratory depression. *Lumbar puncture* should be performed for diagnostic purposes, and should be repeated mainly in order to relieve severe headache. It probably is not worthwhile to repeat lumbar puncture at intervals merely in order to reduce the cerebrospinal fluid pressure or in an attempt to prevent arachnoidal scarring. If there is evidence of intracerebral hematoma, which may be expanding or may be demonstrated by a shift of a calcified pineal on skull x-ray, lumbar puncture should be avoided.

Adequate statistical data are not yet available concerning the effect of *surgical therapy*. Since the general mortality rate with conservative medical management drops to less than 20 per cent after the first 7 to 14 days, the combined procedures of angiography and operation should produce better results than this in order to be considered worthwhile. *Internal carotid artery ligation* has been performed as a relatively safe treatment for aneurysms of this artery (Black and German, 1953); however, it often is ineffective, and there is a risk of complication, such as persistent hemiplegia and aphasia. These complications occur even though it is recommended that the ligation should not be performed unless the patient has tolerated preoperative transient occlusions of up to 15 min and, in operation, compression for at least 30 min without developing symptoms.

There are differences with regard to location of aneurysms. Aneurysm of the anterior cerebral or anterior communicating artery appears to be the most dangerous, being subject to recurrent fatal hemorrhage more frequently than any of the others. The major procedures of *craniotomy* and direct surgical approach to the aneurysm, such as *ligation* or *trapping* on both sides, have had a generally high morbidity and mortality. Emergency intracranial surgery of ruptured aneurysm in the acute stage had an immediate mortality of over 75 per cent. However, newer surgical techniques with hypothermia have greatly reduced these com-

plications (Botterell et al, 1958), and operation now has been advised during the first week, especially in order to limit the effects of vasospasm and further hemorrhage, particularly in patients under 55 years of age who are not comatose (Pool et al, 1959). These techniques have *reduced surgical* mortality to between 20 and 30 per cent. If the patient has survived 3 weeks (Norlen and Olivecrona, 1953), the risk of operation should compare with that in nonoperative management. It is, however, after this period that the risk of recurrent bleeding is much less. There still remains a great need for the accumulation of well-documented critical results from many clinics with long follow-up observations.

REHABILITATION AFTER CEREBROVASCULAR ATTACKS [2]

Patients who have had cerebrovascular attacks with infarction or hemorrhage and have *recovered after the acute stage* usually have a *hemiplegia* in varying degree, about one-half of them have *dysphasia. Hemisensory deficits* and *hemianopsia* also may complicate the picture. These conditions all represent problems in rehabilitation Hemiplegia *is neither static* nor stereotyped, it varies greatly from patient to patient The process *of recovery is a* constantly evolving series of reactions (Twitchell, 1951).

With the onset of the *hemiplegia*, the affected limbs are completely paralyzed, usually with diminution of tendon *reflexes and* flaccidity Within 48 hr, the tendon *reflexes* become hyperactive, and resistance to passive movement increases in wrist and finger *flexors* and in plantar flexors of the ankle This resistance, *or* spasticity, becomes more intense gradually and appears in other muscle groups, particularly *the flexors* and abductors in the upper limbs, and the extensors and abductors in the lower limbs. The tendon reflexes gradually become *more* hyperactive, with clonus, especially at the ankle, a positive Babinski's sign is elicited. *Voluntary* movement returns first as flexion at the shoulder and hips, later, as flexion at the elbows, wrists, and fingers, eventually as knee and ankle flexion Any attempt at willed movement results in flexor synergy, or combined flexor movements, throughout the entire upper or lower extremities. As spasticity becomes more severe, especially during the second and fourth weeks, flexion contractures develop at the hands and elbows and a tightened Achilles tendon impairs foot movements.

Physical therapeutic and rehabilitative procedures (Lowman, 1948) are begun during the first week after the cerebrovascular attack, often within the first 2 days if the patient is cooperative. These measures during the acute phase have been described above. During the next few weeks, the patient is encouraged to start a program of progressive movement. Many patients may be helped into a sitting position during the first week, and even into momentary standing This may be very effective in enabling the patient to maintain a sense of body position. While in bed, the patient should be able to exercise the upper and lower extremities with overhead pulleys *and ropes in* order to reestablish patterns of reciprocal motion In addition, quadriceps-strengthening exercises *and active exercises* of the arm muscles are instituted in order to reestablish normal patterns of movement. It is recommended that the patient begin self-care activities, such as *feeding*, washing, and dressing, as early as possible. If the patient is dysphasic, attempts at *speech therapy* should be started shortly after initial evaluation of the deficit. *The* results of properly applied techniques of rehabilitation in patients with chronic effects of cerebrovascular accidents, such as hemiplegia, show *that* about 85 per cent of these patients will *be able* to walk and take care of themselves generally, and that over 30 per cent will be able to become gainfully employed

Many patients have severe problems of *psychologic deficit*. Lesions of the dominant hemisphere cause dysphasia, alexia, agraphia, and agnosia, with disturbing, often slow, and varied recovery rates (Wepman, 1951). Many patients experience a *syndrome of denial*, either of part of the involved side of the body, or of the fact that the part is paralyzed, especially during the early phase of the accident This form of denial, which occurs particularly in patients with *a minor hemisphere lesion*, has been called *anosognosia* In other patients with major or minor parietal lobe involvement, a cortical sensory deficit with loss of acute discriminating powers makes the use of the extremity in physical therapy most difficult. Brain damage produces both qualitative and quan-

[2] See also Part 20, Chap 3. *Editor.*

titative deficits in intellectual functions, and often it is worthwhile to determine the intensity of these deficits by *psychologic testing*. Projective tests of personality structure and emotional reactions also may be of benefit. The preillness personality configuration and resources of the patient generally determine his reaction to his disabilities and his response to a rehabilitation program. Brain damage may produce, in addition to a language or comprehension disturbance, confusion, affective disturbance, such as depression and irritability, compulsiveness, and many secondary somatic complaints. These may increase during times of stress when new responsibilities and activities are added in the program of rehabilitation.

Factors that complicate or prolong recovery and limit the extent of rehabilitation, therefore, are marked *spasticity*, severe *sensory deficit*, prolonged *flaccidity of extremities*, continued *disorientation and confusional states*, pre- and postillness *personality problems*, and certain medical complications such as pulmonary, cardiac, or renal disturbances. It is best to adapt the rehabilitation procedures to the individual, with but a few general rules. The program should be supported by a complete hospital team, involving physician, nurse, physical therapist, and social worker The family must be brought into the situation and should be reassured and encouraged along with the patient The tasks given to the patient should proceed from the very simple, while he is in bed, to the more complex tasks, such as carrying out the activities of daily living, without exceeding at any time the ability at the moment to perform these tasks The patient should be placed on a program of increasing self-attendance and self-responsibility. Often the use of mild sedatives, such as barbiturates and stimulants, is helpful In addition to the described activities of physical therapy, a daily schedule of recreation, social contact, and occupational therapy should be organized

Patients with *embolic cerebral infarction* secondary to cardiac disease with atrial fibrillation often are limited in their physical rehabilitation by diminished cardiac reserve and by the danger of recurrent embolization. In such patients, atrial fibrillation has been converted to regular sinus rhythm by *quinidine* Significant improvement in hemodynamics and clinical efficiency then occurred (Sokolow et al., 1956).[3]

The problem of *spasticity* is extremely important; there is still no really effective physical or pharmacologic means of relieving the state maximally in order to improve the function of the involved extremity. Spasticity, primarily due to hyperactivity of proprioceptive reflexes, is the primary factor in the production of severe flexion contractures in the upper extremities and of extensor fixations in the lower extremities. In addition, *ankle clonus* appears along with spasticity, often interfering greatly with the ability of the patient to apply pressure and to support himself on the involved lower extremity. The more or less fixed position of the foot in plantar flexion produces a tendency to tightness and shortening of the Achilles tendon, which is difficult to relieve, except by stretching and surgical procedures. Certain "antispastic" drugs have been developed but are still in the process of evaluation. Their effectiveness following oral administration is minimal, but they may relieve spasticity enough in some patients to enable more effective mobility. The drugs in this group are *Myanesin*, *Paraflex*, *Robaxin*, and *Trancopal*.

Soon after a cerebrovascular attack, as the patient becomes aware of his general condition, it is worthwhile to present to him and his family a definite plan of self-care and eventual ambulation It has been stated that if a patient can move his arms slightly or raise his affected leg at least 1 in. from the bed, he will be able to walk again As soon as the medical situation warrants (which is generally within 10 days to 2 weeks), the patient should make attempts to walk. Being able to stand erect and to begin walking exercises has a great effect on morale. Preliminary walking with parallel bars is a safe, easy method of developing correct walking patterns with reciprocal motion. The usual hemiplegic patient will learn to walk outside the bars with one cane and will usually continue to use one cane Actual crutch walking probably will not be necessary. When not involved in walking exercises, the patient should be sitting in a wheelchair, eventually he should be allowed to push his own chair. Because *wheelchair contractures* de-

[3] Another significant step is the use of anticoagulants (see Part 21, Chap. 13). *Editor.*

velop so rapidly, in both the affected and unaffected legs, no patient should spend the entire waking day sitting in a wheelchair or in any other chair. Wheelchair contractures are 90° knee flexion contractures with shortening of the shorter hamstring muscles and consequent stretching and weakening of the quadriceps muscle. Exercises of the quadriceps muscle are extremely important. This muscle must be kept strong enough, if possible, to lift the leg against gravity, otherwise, the knee will buckle as the patient stands. Many patients (up to 60 per cent of them) will need some type of support for the paretic leg—either a short leg brace with a foot drop attachment, or a long leg brace with foot drop correction and lock at the knee. These braces are not to be ordered until at least 3 months after the onset of the cerebrovascular attack, when it becomes apparent that muscle return will be insufficient for stable walking. Temporary bracing may be used in the interim.

For the upper extremities, *forearm splints* may be applied, with dorsiflexion or "cock-up" support, and often with elastic bands for finger exercises. The hand and fingers also may be exercised well with a rubber ball.

The activities of daily living involve those of caring for one's self in bed, eating, dressing, and using utilities and communications. Later on, the patient is taught to walk up ramps, around curbs, up stairs, and across streets, and, progressively, to get in and out of automobiles and public conveyances. Care should be taken, however, to work within the limits of fatigue of the patient; an elderly patient's attention to cardiac status is important.

Emphasis, therefore, in rehabilitation, is first on the development of activities of daily usefulness and living. Concentration then is usually on the lower extremity because of the importance of walking. Upper extremity involvement is more difficult to treat, since it may be less responsive in recovery and since fine movements in the fingers most often do not recover significantly. There are certain limits that should be considered. Usually there should be some response during the period of 4 to 6 months of intensive treatment within an out-patient or hospital setting. An intensive program may be dropped after this, although some treatment should be continued for 6 to 18 months.

Chronic pain syndromes may develop in the hemiplegic patient. Some of these are related to the contractures caused by spasticity and will respond partially to the administration of analgesics and antispastic drugs, and to physical therapy in the form of warm moist applications and baths. Fixations of the shoulder and hand may be painful, in these instances the best therapy is really prevention by early institution of passive and active motions. In some patients a *thalamic syndrome* associated with the hemiplegia results in spontaneous pain and burning sensations (*thalamic pain*), which often are unbearable. The therapy in these situations is extremely difficult; no form of treatment has been satisfactory. However, spontaneous improvement is relatively common.

titative deficits in intellectual functions, and often it is worthwhile to determine the intensity of these deficits by *psychologic testing*. Projective tests of personality structure and emotional reactions also may be of benefit. The preillness personality configuration and resources of the patient generally determine his reaction to his disabilities and his response to a rehabilitation program. Brain damage may produce, in addition to a language or comprehension disturbance, confusion, affective disturbance, such as depression and irritability, compulsiveness, and many secondary somatic complaints. CLINICAL MATERIAL

Table 15-14 summarizes the authors' experience with 146 patients operated upon for cerebral arterial insufficiency during the past 4½ years. The majority of these patients had occlusion of the proximal end of the internal carotid artery. *Carotid endarterectomy* was possible in all patients with partial occlusion. *Removal of the thrombus* and restoration of cerebral flow were accomplished in 3 of 8 patients with complete occlusion of the internal carotid artery. Eight patients were treated for occlusion of the vertebral artery, blood flow was restored in 7 of them. Bypass Dacron grafts were required for occlusion of the innominate and common carotid arteries in 13 patients. All these grafts have remained patent. Eleven of this group have been followed for 2 to 4 years In addition to these patients, 10 others had explorations of the neck for a suspected lesion of the carotid bifurcation. No significant lesion was found. It was assumed that in these 10 patients occlusive lesions were intracranial

Table 15-14. Summary of Data on 146 Patients with Cerebral Arterial Insufficiency

Location of lesion	No of patients	Incomplete occlusion	Complete occlusion
Internal carotid arteries	123	115	8
Vertebral artery	8	7	1
Common carotid artery	10	2	8
Brachiocephalic artery	3	0	3
Carotid exploration *	10	0	0

* In addition to these 146 patients, 10 others had explorations of the neck for a suspected lesion of the carotid bifurcation No significant lesion was found.

PATHOLOGY

Arteriosclerotic occlusive lesions of the carotid and vertebral systems have a characteristic topography. According to Adams and Fisher (in press), atherosclerosis implicates arteries 0 2 mm or more in diameter Branching, junction, and curves are favored sites for the formation of plaques Identifiable plaques rarely appear in vessels less than 0 2 mm in diameter The cervical portion of the internal carotid artery was shown to be the earliest and most consistent part of the vascular system to be involved. Atherosclerosis renders the arteries susceptible to several pathologic changes which are of critical importance to the circulation of the brain As the lumen of the artery becomes narrowed, the blood flow through the vessel is reduced Symptoms are not produced, however, until a critical point is reached, when collateral circulation is inadequate or when it is altered, because of a temporary episode of hypotension, cardiac failure, or change in blood viscosity The intima gradually thickens and ulcerates, and finally leads to thrombosis. The cerebral lesions that follow upon thrombosis exhibit wide variations, depending on the location of the lesion, collateral vascular channels, and probably other factors, such as level of blood pressure, degree of vasoconstriction. and extent of propagating thrombus. It is well known that after gradual occlusion of a major cerebral artery in the neck, collateral circulation develops via the circle of Willis. The importance of this system has been adequately demonstrated by angiographic studies. Anatomic experiments by Vander-Eecken and Adams (1952, 1953) have shown that in the human brain there are direct pial arterial anastomoses between all the major cerebral vessels which provide additional collateral circulation distal to the circle of Willis Repeated angiograms at intervals following carotid ligation show that these collateral vessels are capable of a great increase in size in a matter of weeks. There are also direct end-to-end anastomoses between the tributaries of the cerebellar arteries and the posterior cerebral artery, which provide collateral circulation when the basilar artery is occluded. From these studies it is apparent that in patients with multiple occlusive lesions restoration of flow in one branch may result in improvement of general circulation of the brain through the above-mentioned collateral channels In the authors' group of 146 patients, 123 had occlusion at the carotid bifurcation. Figure 15-42 demonstrates other occlusive sites amenable to surgical correction Although complete occlusion of the internal carotid and vertebral arteries may occur insidiously, it is usually associated with a typical group of symptoms recognized as a "stroke" If the collateral flow is inadequate, brain infarction develops shortly after occlusion becomes complete, and the damage becomes irreversible. As the origin of the internal carotid or vertebral artery becomes blocked, the thrombosis progresses distally and

Surgical management of cerebral arterial insufficiency

HUSHANG JAVID AND WILLIAM S. DYE

The increasing prevalence of cerebrovascular accidents resulting from atherosclerotic occlusion has created serious social and economic problems. According to a study made by Meyer et al. (1955), 33 per cent of all autopsies performed showed a significant degree of cerebrovascular disease. A similar study by Adams and Vander Eecken revealed the incidence to be 20 per cent of all necropsies. A careful study of 1,018 patients by Robinson et al. showed that the initial attack of cerebral thrombosis was fatal in 21 per cent of cases. Fifty per cent of the 747 patients who survived one episode of thrombosis died within 4 years; only 18 per cent of a comparable sample of the general population died within the same period Adams et al. (1957) demonstrated that in patients dying of cerebral thrombosis, transient ischemic attacks were present prior to the final episode in 53 per cent In 18 per cent "stroke" came on in a stepwise manner, with or without transient cerebral ischemia In only 17 per cent of patients was the stroke a single event According to these and other studies, it seems apparent that the majority of patients who develop cerebral thrombosis or die from it have had adequate warning to permit recognition of a vascular occlusion before the final attack occurs

The most common cause of *cerebral thrombosis* is arteriosclerosis. The significance of this lesion in patients with cerebral arterial insufficiency was recognized by Chiari (1905) and by Hunt (1914). Involvement of brachiocephalic branches by atheromatous lesions was described by Broadbent (1875) and by Penzoldt (1881). Chiari emphasized the frequency of atherosclerotic changes of the carotid bifurcation and thought that the cerebral symptoms associated with this lesion were due to embolic phenomena. Advanced stages of occlusion of brachiocephalic branches were described by Takayasu (1908). He noted *a syndrome characterized by loss of pulsation in the arteries of the upper extremity, associated with syncope, visual disturbances, and changes in cerebral function.* The majority of his patients were young Japanese women. The occlusion was considered to be due to inflammatory process. Martorell and Fabre (1944, 1954) described the clinical picture of occlusive lesions of the aortic arch branches. Fisher (1954) reported 45 carotid artery occlusions among 432 autopsies on chronically disabled veterans He found that in spite of severe involvement of the carotid bifurcation, the intracranial vessels were relatively free of disease. This and other observations led to the application of operative procedures that had proved effective in other segmental arterial occlusions Eastcott et al reported the first successful reconstruction for carotid occlusion which resulted in relief of symptoms. Since that time, direct arterial surgery has been employed with increasing frequency in the treatment of cerebral arterial insufficiency.

carotid and vertebral systems. These patients, in the opinion of the authors, deserve correction in multiple stages. Results are gratifying.

DIAGNOSIS

Occlusive lesions of the carotidovertebral system usually occur in two general areas, the origin of the internal carotid artery and the vertebral artery. Proximal lesions, involving branches of the aortic arch, may produce ischemic manifestations of the upper extremities in addition to cerebral vascular insufficiency. These lesions are readily diagnosed by physical findings. A diminished carotid or subclavian pulse, or the absence of one, immediately draws attention to the involvement of the *brachiocephalic branches.* When neck pulses are normal, differentiation between the intracranial cerebrovascular disease and occlusive lesions of the internal *carotid* and *vertebral* systems at the neck level often becomes difficult. A vascular lesion should be suspected when the following features are presented by the patient: (1) attacks of transient cerebral insufficiency, (2) rapid reversal to normal, (3) signs of atherosclerosis elsewhere, (4) hypertension and diabetes mellitus, (5) preservation of consciousness in the presence of a significant neurologic deficit, (6) onset of symptoms at rest or upon rising (state of hypotension).

Symptoms of carotid insufficiency *differ to* some degree from those of vertebral-basilar insufficiency. Patients with *carotid insufficiency* usually experience blurring of vision or temporary blindness on the side of occlusion, associated with hemiparesis or hemiplegia on the opposite side. Aphasia is present *when the left* carotid is involved. Light-headedness is the most common complaint. *Vertebral insufficiency* is manifested by vertigo, double vision, bilateral dim vision, ataxia, and other bilateral neurologic abnormalities.

Physical examination is most helpful in localizing the offending lesion by *revealing*

1. Diminished common carotid *pulsation with bruit* over the base of *the neck, this* indicates occlusion of the *proximal* end of this vessel.

2. Diminished common carotid pulsation without *a bruit,* this may occur in complete internal carotid *occlusion.* Since the flow through this artery is decreased, the pulsation appears diminished.

3. *Bruit* over the base of *the neck* without transmission along the carotid or subclavian vessels, this may be the result of stenosis of the vertebral artery.

4. Palpation of a firm nodule at the level of the carotid bifurcation accompanied by a bruit is highly suggestive of an occlusive lesion of the internal carotid artery. A bruit may be missing in the presence of relatively mild or extremely severe stenosis. A continuous bruit was noted in several patients with marked narrowing of the internal carotid artery and inadequate collateral supply.

5. Palpation of the internal carotid artery through the tonsillar fossa should be attempted, as it may be of help in the diagnosis in some patients. This is not consistently successful, however, since transmitted pulsations from the external carotid artery may render the examination unreliable.

6. *The superficial temporal artery pulsation* may be diminished in *advanced carotid bifurcation lesions,* or it may be increased in cases of *internal carotid occlusion due to increased* compensatory flow.

7. *Carotid compression* may result in *syncope* or *convulsive seizure,* suggesting significant narrowing *of the* opposite carotid artery.

8. *Ophthalmodynamometry* may reveal a reduced *pressure* in *the* central retinal artery, providing a reliable sign. This examination requires considerable skill and, even in the hands of an experienced examiner, has certain limitations. Severe occlusive lesions have been demonstrated arteriographically and at operation in patients in whom the retinal artery pressure was thought to be normal.

9. *Angiography* is most helpful in making the accurate diagnosis of the location and the *degree of* arterial disease. In about 40 per cent *of the patients* who have symptoms of cerebral arterial insufficiency, occlusive lesions can be demonstrated *in* the major arteries supplying the brain. Three methods have been used to visualize brachiocephalic branches.

1. *Intravenous angioaortography.* After introduction of 90 per cent Hypaque solution into the superior vena cava or right atrium, serial pictures demonstrate lesions of aortic arch branches and at times permit visualization of vertebral and internal carotid arteries.

2. Retro...

(Fig. 15 ... ...ation, and cerebral branches

...nt Hypaque solution

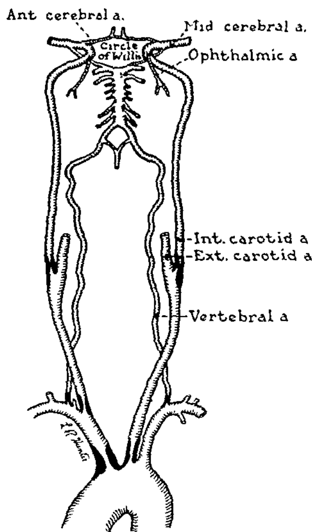

Fig. 15-42 Common sites of occlusive lesions of the carotid and vertebral system

terminates at the level of the first large branch. After the thrombus has become organized, clearing of the vessel is surgically impossible It is, therefore, extremely important to become familiar with the clinical picture of *cerebral arterial insufficiency* resulting from stenosis of these arteries if the aim is prevention of cerebral infarct

CLINICAL FEATURES

Clinical manifestations of cerebral arterial insufficiency are variable and depend upon the location and extent of the lesion Although classification of patients with cerebrovascular disease is difficult because of the complexity of symptoms, the authors have, for the sake of convenience, divided their group into three categories

Category I. Patients in this group usually experience *intermittent attacks*, which differ to some degree, depending upon whether the carotid or the vertebral system is involved. These patients usually recover from this so-called *little-stroke syndrome* spontaneously and show no evidence of residual abnormality. Episodic loss of function, which is supposedly ischemic, is due not to sudden vascular occlusion but to temporary failure of the compensatory mechanism. The cause of this transient deficit is not well understood, although alteration in the blood pressure (Corday et al.) and viscosity of blood (Millikan et al.), changes in local carbon dioxide concentration (Johnson), cerebrovascular resistance, and *embolic phenomena* (Chiari) have been suggested. It is well understood, however, that increase of carbon dioxide, decrease of oxygen, or decrease of pH causes decreased cerebrovascular resistance, resulting in increased flow and correction of local ischemia. This may play an important role in the recovery after transient ischemic episodes. Patients in this category exhibit *partial occlusion of the internal carotid artery or vertebral artery* and, therefore, are amenable to surgical correction. Several of the authors' patients in this category had *complete occlusion of the brachiocephalic or common carotid artery* and responded well to corrective surgery.

Category II. The majority of patients in this group have a longer history of intermittent cerebral ischemia. In addition, they present the picture of a "stroke" resulting from *cerebral infarct*. Although recovery occurs, often some residual neurologic abnormality persists It is most discouraging to treat patients in this group When the clinical picture denotes brain damage, operative procedure is ineffective in correction of cellular damage. *Thrombectomy* may be indicated shortly after occurrence of the stroke in order to restore blood flow and improve the prognosis for protecting other parts of the brain

Category III. The diagnosis in this group of patients presents a great challenge. Symptoms are usually varied and vague, and are slowly progressive over a period of many months *Dizziness*, loss of efficiency, impairment of memory and concentration powers, and generalized muscle weakness are among the most common complaints *Visual disturbance* is common and may include visual field defects. These patients are in the older age group and have evidences of generalized arteriosclerosis of many years' duration. Study, as a rule, demonstrates *multiple occlusions of the*

Surgical intervention in the presence of acute occlusion of the carotid artery is often disappointing. If surgery can be performed shortly after occlusion occurs, it may be possible to remove a fresh thrombus and correct the narrowing by a *local endarterectomy* The use of *heparin* solution for irrigation of the internal carotid artery under low pressure may also be helpful in evacuating the internal carotid artery. It has been the authors' experience, however, that when the hemiplegia is established, clearing of the thrombosed artery does not affect the speed of recovery. Restoration of blood flow may be of benefit in improving the prognosis of the patient, since other brachiocephalic branches may become occluded in time

Occlusions of the common carotid artery, innominate artery, and subclavian artery have been treated with a *bypass procedure* in 13 patients The use of a crimped Dacron graft bypassing these occlusive lesions has proved most satisfactory. A *graft* between the ascending arch of the aorta and the common carotid artery has been used in four patients with lesions of the innominate artery. Four patients with left common carotid occlusion were treated with bypass grafts between the left subclavian and left common carotid arteries. In two patients, a bifurcation graft was used to bypass occlusions of the left common carotid and left subclavian arteries in one person, and of both common carotids in the other. Three remaining patients had significant occlusion of the left common carotid artery and its bifurcation, in addition to severe stenosis of the left subclavian artery. A Dacron tube between the ascending arch and the left internal carotid artery was used in these patients. The ascending arch of the aorta is approached through a midsternotomy incision; the subclavian artery, through a transverse supraclavicular incision

Extreme care must be exercised during dissection in order to eliminate embolic lesions in those patients in whom atheromatous substances may adhere loosely to the wall of the artery. Occasionally, thickening of the intima extends distally and involves a significant portion of the internal carotid artery It is appropriate in such a situation to be content with a *limited endarterectomy* and to enlarge the lumen with a *patch graft* When the intima is thickened and adheres poorly to the outer wall, interrupted sutures may be necessary to

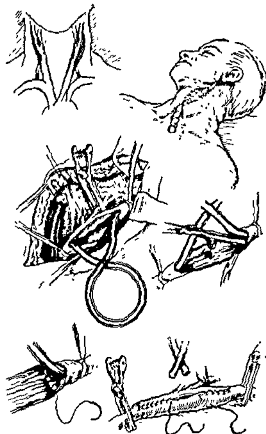

Fig. 15-45. Steps of carotid endarterectomy under local anesthesia using a temporary bypass shunt.

secure the intima to the wall and prevent its dissection Postoperative *anticoagulant therapy*, in the form of subcutaneous heparin administered every 6 hr, has been used for temporary periods up to 1 week. Hypotensive episodes occurring during surgery or in the postoperative period should be treated promptly and energetically.

Results of Surgery. Surgical results are tabulated in Table 15-15. Three patients died in the immediate postoperative period: *myocardial infarct* was the causative factor in one death, and *cerebral infarct* in the other two Unilateral neurologic deficit developed in four patients *Muscle weakness* of the arm was noted immediately following surgery in three patients, despite patency of the endarterectomized segment. Paresis in these patients gradually resolved A hypertensive, diabetic, middle-aged man developed *hemiplegia* and *coma* 2 days after carotid endarterectomy. Spinal puncture revealed the presence of blood in the spinal fluid Response to hypothermia and urea

Fig. 15-43. Percutaneous carotid arteriogram showing marked stenosis of the proximal end of the internal carotid artery with irregularity of the carotid sinus.

has been used in well over 100 cases without any harmful effect.

3. *Percutaneous subclavian arteriogram* is the most satisfactory method for visualizing the proximal end of the vertebral artery.

TREATMENT

Since therapeutic measures are of no benefit when a fully developed cerebral infarct has been established, it is most essential that emphasis be placed on prevention. Fundamentally, this means the eradication of atherosclerosis. Until this is achieved, every attempt should be made to recognize vascular lesions in their preocclusive stage and correct them surgically. The use of *anticoagulants*, although often effective, has certain limitations. It depends upon collateral circulation and preventing extension of the occlusive process. Unfortunately, many of these lesions are multiple, therefore, development of collateral channels is limited. Furthermore, the arteriosclerotic changes are progressive, and complete obstruction eventually takes place in spite of anticoagulant treatment.

Restoration of blood flow has been possible in all patients in category I. Partial occlusion of the internal carotid or vertebral arteries has been treated by *local endarterectomy*. Carotid bifurcation is readily approached through a longitudinal incision in the neck under local anesthesia. Atheroma is removed by careful separation of the intima from the outer wall of the artery (Fig. 15-44). In patients who have multiple occlusions, and in those who do not tolerate compression of the carotid artery, a *temporary internal shunt* is used (Fig. 15-45). Occasionally the carotid sinus is narrow and the use of an *autogenous vein patch* or a *prosthesis* is necessary to provide adequate lumen. Lesions of the proximal end of the vertebral artery may also be approached through a neck incision, but because of the depth of dissection, general anesthesia is preferred. The use of *local endarterectomy, arterioplasty,* and an *autogenous vein graft patch* is often necessary to correct the involved segment.

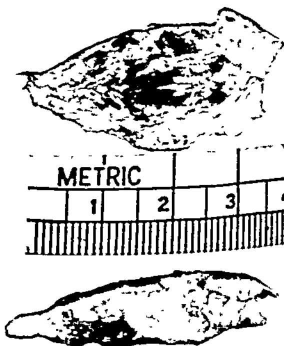

Fig. 15-44. The specimen obtained in endarterectomy of the carotid bifurcation.

Surgical intervention in the presence of acute occlusion of the carotid artery is often disappointing. If surgery can be performed shortly after occlusion occurs, it may be possible to remove a fresh thrombus and correct the narrowing by a *local endarterectomy.* The use of *heparin* solution for irrigation of the internal carotid artery under low pressure may also be helpful in evacuating the internal carotid artery. It has been the authors' experience, however, that when the hemiplegia is established, clearing of the thrombosed artery does not affect the speed of recovery. Restoration of blood flow may be of benefit in improving the prognosis of the patient, since other brachiocephalic branches may become occluded in time

Occlusions of the common carotid artery, innominate artery, and subclavian artery have been treated with a *bypass procedure* in 13 patients The use of a crimped Dacron graft bypassing these occlusive lesions has proved most satisfactory. A *graft* between the ascending arch of the aorta and the common carotid artery has been used in four patients with lesions of the innominate artery. Four patients with left common carotid occlusion were treated with bypass grafts between the left subclavian and left common carotid arteries. In two patients, a bifurcation graft was used to bypass occlusions of the left common carotid and left subclavian arteries in one person, and of both common carotids in the other Three remaining patients had significant occlusion of the left common carotid artery and its bifurcation, in addition to severe stenosis of the left subclavian artery A Dacron tube between the ascending arch and the left internal carotid artery was used in these patients. The ascending arch of the aorta is approached through a midsternotomy incision; the subclavian artery, through a transverse supraclavicular incision

Extreme care must be exercised during dissection in order to eliminate embolic lesions in those patients in whom atheromatous substances may adhere loosely to the wall of the artery Occasionally, thickening of the intima extends distally and involves a significant portion of the internal carotid artery. It is appropriate in such a situation to be content with a *limited endarterectomy* and to enlarge the lumen with a *patch graft* When the intima is thickened and adheres poorly to the outer wall, interrupted sutures may be necessary to secure the intima to the wall and prevent its dissection. Postoperative *anticoagulant therapy,* in the form of subcutaneous heparin administered every 6 hr, has been used for temporary periods up to 1 week. Hypotensive episodes occurring during surgery or in the postoperative period should be treated promptly and energetically.

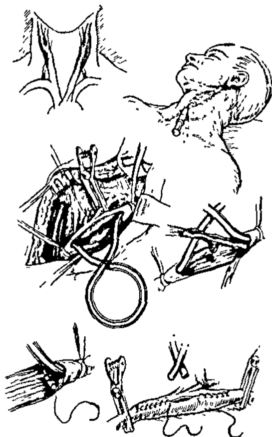

Fig. 15-45. Steps of carotid endarterectomy under local anesthesia using a temporary bypass shunt.

Results of Surgery. Surgical results are tabulated in Table 15-15. Three patients died in the immediate postoperative period. *myocardial infarct* was the causative factor in one death, and *cerebral infarct* in the other two. Unilateral neurologic deficit developed in four patients Muscle weakness of the arm was noted immediately following surgery in three patients, despite patency of the endarterectomized segment. Paresis in these patients gradually resolved A hypertensive, diabetic, middle-aged man developed *hemiplegia* and *coma* 2 days after carotid endarterectomy. Spinal puncture revealed the presence of blood in the spinal fluid Response to hypothermia and urea

was outstanding; after 1 week, this patient began to respond and he recovered completely from the episode. He has remained asymptomatic for the past 6 months.

Patients in category I are well suited for surgical intervention. Eighty per cent of these patients have remained asymptomatic following surgery; an additional 12 per cent have improved significantly.

In category II, surgical intervention is contraindicated unless operation can be performed shortly after acute occlusion occurs. The authors have seen 25 patients with complete occlusion of either the internal carotid or the vertebral artery. Eight patients of this group were operated upon. Blood flow was restored in only three: two were greatly benefited by surgery; one died from extension of thrombosis.

Patients in category III were carefully studied prior to surgery. Neurologic examination, electroencephalogram, psychometric studies, and ophthalmodynamometric readings were recorded in the majority of these patients. A remarkable response was noted in some, including significant improvement in memory, ability to concentrate, and a reversal of abnormal EEG. Six patients in a group of 16 have remained asymptomatic since surgery.

SUMMARY

Clinical features of patients with cerebral-arterial insufficiency were classified into three categories. The ideal candidate for endarterectomy is the patient with partial and segmental occlusion of the internal carotid artery and vertebral artery. Bypass graft with crimped Dacron tube is preferable in more extensive lesions of the common carotid, brachiocephalic artery, or subclavian artery. Complete occlusion of the internal carotid artery is not operable. Therefore, great emphasis should be placed on diagnosis of symptomatic arterial stenosis.

TABLE 15-15 SURGICAL RESULTS IN 146 PATIENTS WITH CEREBRAL ARTERIAL INSUFFICIENCY

	No. of patients	*Treatment, with no. of operations*	*Restoration of blood flow*	*Absence of symptoms*	*Improvement*	*Occurrence of late thrombosis*	*Death in immediate postoperative period*
Category I	122	Endarterectomies, 123 *, grafts, 10	122	98	15	2	1
Category II	8	Endarterectomies, 8	3	2	1	0	1
Category III	16	Endarterectomies, 27 †, grafts, 3	16	6	5	1	1

* Eleven patients had bilateral carotid endarterectomy.
† Thirteen patients had bilateral endarterectomy; 1 patient had both graft and endarterectomy.

I

Less common causes of cardiovascular disease[1]

NATHANIEL E. REICH

An arbitrary selection and discussion of the less common causes of cardiovascular disease must of necessity be sharply limited in order to keep within the requirements of an introductory chapter Obviously, they cannot be discussed in any great detail, nor can extremely rare or bizarre conditions be included.

NONSTRUCTURAL CARDIOVASCULAR ABNORMALITIES

Many unrelated conditions of essentially nonorganic nature can affect the cardiovascular apparatus Changes in the normal rhythm or the appearance of symptoms and signs are the most common sequelae. They do not produce appreciable structural changes, except in rare instances. However, these conditions frequently precipitate or aggravate latent or unknown heart disease They may even produce temporary exhaustion of the normal cardiac reserve A disastrous outcome is *possible in* rare instances, such as *cardiac standstill* occurring during surgical operations Electrocardiographic alterations are of vital importance in their diagnostic and prognostic evaluation. Of course, the electrocardiographic findings must be balanced with the history, physical examination, roentgenograms, blood studies, and exercise and other specific tests. The effects of work and exercise, atmospheric pressure, anesthesia and surgery, and electric shock will be discussed below.

Effect of Work and Exercise on the Heart. Although it has been shown repeatedly that strenuous training or unusual exertion extended over a long period of time may produce cardiac enlargement, this increase is distinctly of a temporary nature In instances in which heart failure has followed excessive physical strain, previously acquired heart disease usually existed. Transitory, nonfatal collapse following severe physical effort in sports or at work may be caused by orthostatic hypotension. This is due to pooling of blood in the dependent lower extremities, probably as a result of dilatation and failure of the muscular venopressor mechanism, and is frequently connected with a disturbed function of the carotid sinus receptors.

Atmospheric Changes. The cardiovascular system is profoundly affected by changes in atmospheric pressure. Characteristic syndromes are produced when individuals are subjected to an atmosphere which is markedly rarefied These alterations may be acute, e g., in sudden airplane climbs or in sudden decompression, as in the rapid return to sea level from the ocean depths, or they may be chronic, with a tendency for adaptation, as in mountain sickness In the latter, there is a close relationship

[1] This chapter has been prepared as an introductory presentation of several disparate topics, which will be discussed in greater detail in the following chapters of this part A few subjects (Mycotic and Parasitic Diseases) have been discussed in Part 8. On the whole, this comprehensive survey seems

Less common causes of cardiovascular disease[1]

NATHANIEL E. REICH

An arbitrary selection and discussion of the less common causes of cardiovascular disease must of necessity be sharply limited in order to keep within the requirements of an introductory chapter. Obviously, they cannot be discussed in any great detail, nor can extremely rare or bizarre conditions be included.

NONSTRUCTURAL CARDIOVASCULAR ABNORMALITIES

Many unrelated conditions of essentially nonorganic nature can affect the cardiovascular apparatus. Changes in the normal rhythm or the appearance of symptoms and signs are the most common sequelae. They do not produce appreciable structural changes, except in rare instances. However, these conditions frequently precipitate or aggravate latent or unknown heart disease. They may even produce temporary exhaustion of the normal cardiac reserve. A disastrous outcome is possible in rare instances, such as *cardiac standstill* occurring during surgical operations. Electrocardiographic alterations are of vital importance in their diagnostic and prognostic evaluation.

[1] This chapter has been prepared as an introductory presentation of several disparate topics, which will be discussed in greater detail in the following chapters of this part. A few subjects (Mycotic and Parasitic Diseases) have been discussed in Part 8. On the whole, this comprehensive survey seems helpful in completing and synthesizing a score of topics which have been called "less common cardiovascular diseases." *Editor*

Of course, the electrocardiographic findings must be balanced with the history, physical examination, roentgenograms, blood studies, and exercise and other specific tests. The effects of work and exercise, atmospheric pressure, anesthesia and surgery, and electric shock will be discussed below.

Effect of Work and Exercise on the Heart. Although it has been shown repeatedly that strenuous training or unusual exertion extended over a long period of time may produce cardiac enlargement, this increase is distinctly of a temporary nature. In instances in which heart failure has followed excessive physical strain, previously acquired heart disease usually existed. Transitory, nonfatal collapse following severe physical effort in sports or at work may be caused by *orthostatic hypotension*. This is due to pooling of blood in the dependent lower extremities, probably as a result of dilatation and failure of the muscular venopressor mechanism, and is frequently connected with a disturbed function of the carotid sinus receptors.

Atmospheric Changes. The cardiovascular system is profoundly affected by changes in atmospheric pressure. Characteristic syndromes are produced when individuals are subjected to an atmosphere which is markedly rarefied. These alterations may be acute, e.g., in sudden *airplane climbs* or in *sudden decompression*, as in the rapid return to sea level from the ocean depths; or they may be chronic, with a tendency for adaptation, as in mountain sickness. In the latter, there is a close relationship

between the severity of *hypoxia* and the degree of myocardial hypertrophy. The average diameter and area of myocardial fibers increase together with the increase in heart weight. The *capillary blood supply is diminished relatively as the thickness of myocardial fibers increases.* This condition approximates that found in other forms of *hypertrophy*. Cardiovascular signs are manifested as tachycardia, cyanosis, dyspnea, palpitation, and elevated *systolic* pressure. Frank heart failure *rarely occurs* at *high altitudes*, unless there is *underlying* heart disease. Marked changes in *the electrical* activity of the heart are primarily related to the *physiological* and chemical variations induced by changes in altitude rather *than by* permanent anatomic changes

When high altitude is reached quickly, pathological changes ensue as a result of *asphyxia*. Among them are increased capillary *permeability*, *hemorrhage*, edema, and perivascular infiltration. Cerebral degenerative changes may occur, as well as hemorrhage in the myocardium, mitral valve, lungs, kidneys, and other organs. Above 18,000 ft, *collapse is generally* due to peripheral circulatory failure. A *rapid* reduction in air pressure during a rapid return *to a normal* atmospheric pressure results in a characteristic syndrome known *as compressed-air sickness (caisson disease)* *This results* from the liberation of nitrogen *bubbles in the blood stream and gives rise to air embolism.* The gas enters the left heart and death may ensue *from* hypoxia or systemic emboli

Anesthesia and Surgery. The normal cardio*vascular system* may be profoundly affected by anesthetics, as well as by *surgical* procedures In fact, the anesthetic *agent is usually* of greater importance than the operative *procedure in the* production of cardiac arrhythmias A large pro*portion of operations* are presently performed under *spinal anesthesia* Of all anesthetic procedures, this method places the *greatest* stress on the circulation, which is directly *related* to the blocking of efferent vasomotor impulses *to* arterioles, venules, and veins. The most significant changes are (1) a decrease *in blood* pressure, (2) a reduction in total *peripheral* resistance, and (3) a decrease in the *stroke* volume of the heart. Acute cardiac or circulatory emergencies may occur during the course of *inhalation anesthesia*. Induced cardiac irregularities *range in severity* from occasional extrasystoles *to ventricular fibrillation.* Minor deviations *in pulse rate,* blood pressure, or cardiac rhythm during anesthesia may assume major proportions in patients with cardiovascular disease. Although disturbances of the cardiovascular system may occur in any type of major *surgery, they* are most frequently found in association with intrathoracic operations.

Electric Shock. Electrical energy may produce deleterious effects of a serious nature on the cardiovascular apparatus. The causative factor may be generated in nature (lightning) or artificially produced (electric current). Either form may result in cardiovascular damage. The therapeutic use of *electroshock* is now limited. Besides burns and asphyxia, the *current may arrest* the heart in a firm tetanic contraction or produce ventricular fibrillation Following electroshock therapy, a great variety of arrhythmias may appear, some of which are potentially dangerous.

Effects of Drugs, Electrolytes, and Toxins on the Cardiovascular System. A surprisingly large number of diffusible drugs and other substances are capable of producing changes in the cardiovascular apparatus. Evanescent abnormalities of variable duration are frequent occurrences. Although the toxic changes, due to individual sensitivity, continued overmedication, or overexposure, are usually benign, *they may end disastrously* on rare occasions These effects also depend upon the inability of a damaged liver to detoxify them or upon *the* presence of kidney disease which prevents their normal excretion Toxic effects are exerted on the myocardium, the conduction system, or the autonomic nervous system. Transitory changes occasionally occur due to relative coronary insufficiency. This effect may be caused by focal or generalized coronary vasoconstriction or a work load on the heart increased beyond the capacity of the coronary arteries to maintain an adequate blood supply to all parts of the heart The effective agents include drugs which act upon the autonomic nervous system as they influence the cardiovascular system, drugs employed in cardiovascular therapy, drugs used in the treatment of infections, industrial toxins, and the toxic effects of diphtheria and uremia.

Stimulants *and depressants of* both the sympathetic and parasympathetic systems exert

various effects at specific sites of the autonomic nervous system. They not only increase characteristic physiological activity but may produce toxic effects on the cardiovascular system For example, *epinephrine* acts on the effector cells of the sympathetic system (see Chap 10 and Part 2, Chap. 29). The metabolic changes elicited in the heart muscle include intercellular edema, hypoxia, and diminution of creatine, phosphagen, and adenylpyrophosphoric acid The pulse rate, cardiac output, stroke volume, and left ventricular work per minute and per beat, as well as systolic pressure, are all significantly increased Electrocardiographic changes show *sinus tachycardia* and decreased voltage of the T waves in all leads In patients with coronary heart disease, there may also be depression of the S-T segment.

Toxic effects on the cardiovascular system consist of palpitation, tachycardia, and elevation of the blood pressure. Epinephrine is capable of causing myocardial hypoxia as a specific metabolic effect, *regardless of hemodynamic* conditions and regardless of the volume of coronary flow Cardiac arrhythmias may appear, and usually consist of *ventricular extrasystoles* or even *fibrillation*. In the presence of hypertensive heart disease or hyperthyroidism, there may be an increased susceptibility to the pressor effect of epinephrine The drug may also induce precordial pain in patients with coronary heart disease, but not in normal persons (except in very large doses)

A large number of drugs have as their primary function the therapeutic stimulation or depression of the cardiac structures, or the constriction or dilatation of the blood vessels These include digitalis and allied cardiac glycosides, quinidine, nitrites and other hypotensive drugs, aconitine, papaverine, mercurial diuretics, the xanthines, and procaine In addition to their specific actions, they exert toxic effects on the cardiovascular apparatus Digitalis derivatives are the most widely used of these drugs. In addition to increasing the force of systolic contraction, they also slow the heart rate by direct action on the conduction system and by vagal stimulation Toxic effects are associated with alterations in cardiac rate and rhythm and may produce almost any type of arrhythmia

Antimony and arsenical compounds, antimalarial drugs, and anthelmintics are commonly employed in various infections and infestations They are also capable of producing toxic myocardial effects (see Chap 8).

Gases and vapors, lead products, pesticides, and industrial solvents may exert toxic effects on the cardiovascular apparatus. *Carbon monoxide* produces myocardial hypoxia by its greater affinity for hemoglobin than that of oxygen. The pathological lesions are primarily vascular and consist of small hemorrhages and perivascular infiltrations with focal necrosis The heart shares in the characteristic "cherry red" staining of all organs and the skin Cardiac symptoms and ECG changes are common *Cyanides* cause asphyxial death by interfering with the respiratory ferments of tissue cells as well as by their toxic effect on the heart

While the main effect of *diphtheria* on the heart is usually due to a potent circulating toxin, direct bacterial invasion of any of the three heart layers is also possible The main toxic effect is the production of parenchymatous degeneration and necrosis and small hemorrhages in the myocardium In nonfatal cases, these areas heal with scarring which frequently involves the conduction system Heart block is most common. Sudden death may occur in overwhelming infections *Uremia* is the symptom complex of toxemia associated with *renal insufficiency*, and is due to the retention of nitrogenous and other end products of metabolism, as well as to profound electrolytic disturbances. These important but unclarified alterations occurring in the uremic state contribute to the development of so-called "uremic heart disease." The toxic effects of uremia produce organic as well as functional changes in the heart In the heart muscle of uremic persons, severe degenerative changes are frequently observed, as well as a diminished creatine concentration, similar to that which follows toxic doses of epinephrine Fibrinous pericarditis frequently occurs as a terminal event.

TUMORS OF THE HEART

The estimated ratio of primary to secondary tumors of the heart is 1:16 Primary tumors of the heart which have been reported have been identified as myxoma, fibromyxoma, sarcoma, fibroma, lipoma, rhabdomyoma, endothelioma, lymphangioma, lymphangioendothelioma, hemangioma, hemangioendothelioma, leiomyoma,

and mesothelioma. Because of their location, even benign tumors may be harmful (see Chap. 6).

Metastatic involvement of the heart may arise from any tissue within the body and arrive at the heart by hematogenous, lymphatic, or direct spread. The most common sources of the primary lesions are the trachea, breast, lung, stomach, esophagus, kidney, and pancreas. The most commonly diagnosed types have obviously been *malignant melanoma*, *primary carcinoma of the lung*, and *lymphoblastoma*.

The greatest difficulty in diagnosis lies in the fact that the major portion of the heart muscle may be invaded without producing symptoms or signs referable to the heart. The variability of the size, number, and position of the tumor masses results in a varied clinical picture. In the case of *metastatic tumors*, symptoms due to the primary lesion may overshadow those of cardiac origin The growing lesions tend to produce an ever-changing clinical picture. Cyanosis, dyspnea, variable arrhythmias, murmurs, and eventual unexplained rapid heart failure, are suggestive features. Pericardiocentesis may reveal characteristic neoplastic cells. Localized irregularities in the cardiac contours may become evident and the ECG changes may suggest the diagnosis.

MYCOTIC AND PARASITIC DISEASES OF THE HEART

Common infections of the heart of *bacterial*, *rickettsial*, and *viral* origin are discussed elsewhere (Part 8). The *mycoses* capable of involving the heart comprise a much smaller group of diseases resulting from widespread infections by pathogenic fungi Although many of these agents are world-wide in distribution, they are of the greatest significance in the tropics, where the climate and poor sanitation provide an especially favorable environment. Diagnosis usually depends upon cultural methods.

Actinomycosis was one of the first diseases recognized as being caused by a fungus About half of the cases with direct extension to the heart show clinical manifestations. Congestive heart failure is most common, but pericardial rubs and murmurs may be present Histologically, suppuration is a feature of all active lesions. The demonstration of the typical sulfur granules and the "actinomycete rosette" in the tissue or exudate is usually sufficient to establish the diagnosis *Blastomycosis* is characterized by suppuration and granulomatous lesions in any part of the body. Although the skin, lungs, and bones are usually involved, the heart and pericardium may also become affected. *Histoplasmosis* and *sporotrichosis* may also affect the heart. More recently, the increasing occurrence of *moniliasis* following the use of many antibiotics has produced a number of instances of mycotic endocarditis and interstitial myocarditis.

Many cardiac diseases of parasitic origin have become universal since World War II. Most protozoan and helminthic infections are quite insidious and chronic and may prove baffling. Recent studies of the incidence and cardiologic characteristics have increased the significance of some of the following diseases

1. Protozoan diseases which are capable of producing cardiovascular involvement: *malaria*, *American trypanosomiasis (Chagas' disease)*, and *sarcosporidiosis*.
2. Helminthic diseases: *trichinosis*, *strongyloidiasis*, *filariasis*, *schistosomiasis*, *heterophyiasis*, *cysticercosis*, and *echinococcosis*.

Hookworm and *fish tapeworm* may produce cardiac dilatation and murmurs because of severe anemia. The parasite *Trypanosoma cruzi* exhibits a distinct preference for the myocardium in the chronic form of the disease It is primarily a disease of young adults. The clinical picture is one of congestive failure which persists for months or years, usually proves resistant to treatment, and finally terminates in death. Myocarditis is the most important complication of *trichinosis* It may appear as early as the second week and may severely affect the myocardium by a direct invasion of the larvae, this results in marked parenchymatous degeneration Advanced myocardial damage may eventually produce the clinical picture of cardiac insufficiency. Species of *Schistosoma* derived from infected snails may involve the lungs with resultant chronic cor pulmonale, or the ova may directly invade the myocardium. Cardiac manifestations are due to localized inflammatory reactions of the foreign-body type. Later, the ova become encapsulated by connective-tissue proliferation

which may then become calcified *Echinococcus* may infest the heart and produce cardiac cysts (see Part 8, Chap 10).

TRAUMA OF THE HEART

The heart may be traumatized by indirect or nonpenetrating direct injuries as well as by penetrating agents (see Chap. 7). *Contusion of the heart* (*contusio cordis*) may occur despite the fact that this vital organ is well protected by the bony thoracic cage and is a mobile structure which can move with the force of the blow. It is likely to follow *steering wheel injuries* and serious falls Contusio cordis mainly results in damage to the myocardium Small hemorrhages are due to rupture of the smaller vessels Actual *rupture of the heart muscle* may occur to a lesser or greater degree Constant oozing results in compression of the heart (cardiac tamponade). *Tamponade* may also be due to pericardial bleeding without actual rupture of the myocardium Softening and fibrosis of a contused area occasionally give rise to the formation of a localized aneurysm

Acute or chronic tamponade is usually the main feature of *penetrating injuries* Most authors disclaim the influence of *trauma* in the causation of coronary thrombosis with myocardial infarction unless there is a direct injury to these vessels. Cardiac involvement may present symptoms of precordial pain, cyanosis, and dyspnea. Arrhythmias or left ventricular failure may also occur. A rapidly changing electrocardiographic picture is significant Compression of the heart produces a characteristic syndrome (tamponade). The increasing pericardial pressure compresses the large veins entering the heart with a resultant decline in arterial pressure and a rise in venous pressure As the condition progresses, the pulse pressure fails, the pulse rate increases, and symptoms of cardiac failure intervene

CALCIFICATION OF THE MYOCARDIUM

Calcification of the myocardium may be considered as of primary origin when the initial pathologic change exists in the myocardium, in contradistinction to secondary types which depend upon mobilization and deposition of calcium in the myocardium as a result of extracardiac causes. *Primary calcification* of the myocardium may occur shortly after birth as a result of either early degenerative or inflammatory processes. Myocardial lesions due to infarction, degenerative disease, or various types of myocarditis, may leave calcium compounds deposited in the affected areas This calcification is considered a late healing stage and occurs most frequently following myocardial infarction. Since circulation is absent in necrotic areas, a slow diffusion of calcium salts takes place from the blood and lymph channels of the surrounding tissues This condition has also been termed "primary massive calcification of the myocardium" Since it is most frequently caused by coronary occlusion, it is most commonly found in the left ventricle Calcification may also occur in the organized thrombus contained within a ventricular aneurysm, as well as in cases of adhesive and constrictive pericarditis (Fig 16-1). Metastatic or *secondary calcification* of the myocardium may be seen in hyperparathyroidism, hypervitaminosis D, and diseases associated with severe osteoporosis, such as osteomalacia and osteitis fibrosis cystica. In these instances, the calcium is removed from the bones and deposited in the heart and other tissues. The calcified areas may be readily visible in motion under fluoroscopic examination.

AMYLOIDOSIS

Amyloidosis is an uncommon degenerative process in which progressive cardiac involvement may be followed by heart failure (see Chap. 5) Amyloid is a foreign material which is produced and deposited in various body tissues The substance is a glycoprotein consisting of two protein and one polysaccharide fractions It is believed either that it is a product of the combination of a component of serum globulin and a fixed component of the vascular system, or that the presence of hyperglobulinemia results in the deposition of excess globulin in the tissues *Primary systemic amyloidosis* is a form of the disease in which no preexisting illness is present and in which the material is often deposited prominently in the heart and other mesodermal structures *Secondary amyloidosis* is associated with preexisting chronic diseases which include syphilis, chronic suppuration, chronic severe anemia. chronic

arthritis, tuberculosis, and malignancy Localized amyloid deposits may be found. Occasionally, amyloidosis is found in association with multiple myeloma. The most remarkable feature of the primary type is that the greatest concentration of amyloid is distributed throughout the myocardium. Atrial and ventricular walls may be thickened, and appear hard, grayish-tan, waxy or translucent, glossy and stiff, or leathery in instances in which amyloid is diffusely distributed Imprisoned myocardial fibers thus may (1) be compressed, (2) degenerate, (3) become necrotic, and (4) finally disappear leaving empty amyloid rings These pericellular deposits may be continuous with amyloid in the blood vessels of the myocardium. Amyloid may also be deposited in the other heart layers and valves and the coronary and pulmonary arteries. Thus, cardiac failure, coronary insufficiency, or valvular deformities may predominate in the clinical picture. Involvement of the lungs and mediastinum may contribute to the cardiac failure by the development of chronic cor pulmonale. Biopsy and Congo-red test are diagnostic. *Low voltage* of all complexes is a prominent electrocardiographic feature.

SARCOIDOSIS

Sarcoidosis is a chronic, benign, granulomatous process of unknown cause mainly involving the lymphatic tissue It may occur at any age but is most frequent between the ages of 15 and 40 years. There is no sex predominance, but Negroes appear to be affected more frequently than Caucasians. Involvement of the myocardium may be due to a focal or diffuse *granulomatous myocarditis* associated with cardiac hypertrophy. Electrocardiographic changes which have been noted include inverted T waves suggestive of myocardial damage, and arrhythmias. Findings are present which also suggest pericardial involvement. *Chronic cor pulmonale* secondary to marked pulmonary sarcoidosis results in signs of right

Fig 16-1. Calcification of cardiac structures A Calcification of mitral ring (2) and aortic leaflet (1), with movements clearly visible on fluoroscopy B Concretio cordis Complete envelopment of the heart. C Concretio cordis Localized envelopment of the heart Angiocardiograms (3-sec film) outlining left atrial wall, which is completely circumscribed by localized calcification of wall (arrows) compressing the pulmonary veins as they enter this chamber.

heart failure and death. Hyperglobinemia, hypocalcemia, negative tuberculin test, skin biopsy, and bony changes are important laboratory data which aid in diagnosis.

UNCOMMON DISEASES OF THE ENDOCARDIUM

Endocardial disease is usually an endocarditis mainly affecting the valves The major etiologic types are discussed in detail elsewhere (Part 8). Besides the common rheumatic fever, bacterial endocarditis, and syphilitic infection, tuberculosis may also affect the valves in rare instances. Bacterial endocarditis may extend to the mural endocardium The thrombotic lesions are sterile in *Libman-Sacks disease* and in other collagen diseases which affect the valves. The occurrence of *fetal endocarditis* has never been established since unequivocal evidence of inflammation is seldom found. It is probably a developmental defect. *Endocardial pockets* resemble valve cusps in form They are usually found on the left side of the interventricular septum and are due to the marked regurgitation of blood resulting from aortic insufficiency. A similar pocket may be produced by the continuous pressure of blood exerted upon the entrance of an aortic stenosis

Fibroelastosis. Considerable attention has been given to the occasional finding of a glistening, white or yellow thickening of the endocardium with or without valvular deformity This fibroelastic tissue has been attributed to inflammatory residuals or developmental defect (see Chap. 12). Because of associated congenital defects and the absence of true earmarks of inflammation, the developmental idea is more acceptable in many instances. Endocardial thickening interferes with the emptying of intraluminal vessels into the ventricles The resulting anoxemia eventually leads to myocardial damage and failure.

In addition to the primary congenital type, an acquired type may also occur Diffuse or circumscribed lesions may be due to a variety of causes. Endocardial thickening may occur following a number of primary lesions of the myocardium. This results from either the healed endocardial element of myocardial infarction or as the end stage of an organized mural thrombus Elastic tissue is absent in such cases. Marked hypertension has never been proved as a factor in children Congenital anomalies of the origin of the coronary arteries usually cause *endocardial fibrosis* as well as myocardial hypertrophy. Circumscribed sclerotic lesions are the seat of old nonrheumatic endocarditic lesions, since the valves are not involved. When the left ventricular wall is dilated and hypertrophied, it resembles that of cases reported as "idiopathic hypertrophy of the heart." The left ventricle is small in the contracted or constrictive type of endocardial sclerosis. This prevents adequate diastolic expansion and eventually gives rise to right ventricular hypertrophy.

UNCOMMON CAUSES OF PERICARDIAL DISEASE

Congenital Deficiency. A defect or total absence of the pericardium has been attributed to a premature atrophy of the left duct of Cuvier owing to an anomaly of the circulation of the great venous trunks. In turn, the arrested development of the primary ridge results in a localized defect of the pleuropericardial septum, which normally develops during the fifth week of prenatal life. This is not incompatible with normal cardiac activity since the function of a frictionless serous sac may be replaced by the pleural cavity. There are no symptoms in uncomplicated cases Roentgenograms in the right and left lateral recumbent positions may reveal wide excursions of the heart.

Coelomic Cyst. Coelomic cyst of the pericardium is of mesodermal origin and of simple anatomic structure. The pericardium arises from a series of disconnected lacunae in the mesenchyme which appear early in embryonic life The failure of a lacuna to merge with the others in the formation of a pericardial coelom, and its progressive enlargement, give rise to a cyst connected or adjacent to the pericardium.

Pneumopericardium. *Pneumopericardium* signifies the presence of gas within the pericardial sac, this is due to a variety of causes. The gas may prove irritating, giving rise to [illegible]

[illegible] infection of the pericardium is usually the cause In lesions causing rupture of the esophagus, examination reveals pericardial tympany and distant heart sounds with

splashing or churning noises due to the presence of liquid and air. Roentgenograms and aspiration reveal specific changes.

Chylopericardium. True *chylopericardium* does occur, and pseudochylous fluids may be aspirated from the pericardial sac following indirect or direct trauma to the thoracic duct or due to neoplastic or tuberculous invasion of the duct. Aspiration of a milky fluid is characteristic. Pseudochylous fluid does not contain fat, but it has a milky appearance due to the presence of fine albuminous particles.

Acute Nonspecific (Idiopathic) Pericarditis. Acute nonspecific pericarditis pursues a relatively benign clinical course without evidence of any associated or primary disease. (See Part 8, Chap. 3.) Recognition of these cases is highly desirable since their differentiation from other types of pericarditis and myocardial infarction is of great importance. Although the causative factor remains obscure, it is a frequent sequela to upper respiratory infections The possibility that the disease represents an antigen-antibody reaction with sensitization of the pericardium and subsequent inflammatory reaction on exposure to bacterial antigen cannot be excluded. A history of recurrent attacks may be obtained in a fair number of cases. This susceptibility to reinfection is similar to that seen in rheumatic fever. The involved areas of the pericardial sac lose their normal glistening appearance and become dull and opaque. Fibrin deposits may advance to the stage where the heart surface has a shaggy appearance ("bread and butter" type). The fibrinous character of the exudate diminishes as the fibrinous effusion appears in variable amounts. The diagnosis rests upon the history of upper respiratory infection, or unexplained fever and other transitory evidence of mild infection Severe chest pain, dyspnea, fever, and pericardial friction rub occur Paracentesis reveals fluid with no bacterial content. Roentgenograms and electrocardiograms are highly distinctive. Elevation of RS-T segments and peaked T waves are characteristic.

UNCOMMON DISEASES OF THE CORONARY ARTERIES

A large number of neglected conditions affecting the coronary arteries may occur, some of which are of increasing clinical importance because they are observed more often.

Most anomalies of the coronary circulation consist of a displacement of the origin of one or the other of the main coronary arteries due to a slightly abnormal location or absence of a primordial vascular bud There is a frequent association with other congenital anomalies, such as transposition of the great vessels Thus, a single coronary artery may occur or the left coronary artery may originate from the pulmonary artery. Subendocardial fibroelastosis has been attributed to the resultant anoxemia. Anomalies of secondary and tertiary branches are also possible. For example, the left circumflex artery may arise from the right coronary artery. Supernumerary coronary arteries and coronary arteriovenous fistulas have also been reported. Congenital necrosis of the media of coronary arteries has also been described (Gruenwald).

Specific infections and parasitic diseases, such as syphilis (see Part 9) and malaria (see Part 8), are considered elsewhere.

Aneurysms of the coronary arteries are usually of congenital or embolic-mycotic origin Arteriosclerosis, syphilis, and collagen diseases have also been at fault on occasion.

Emboli may interfere with the coronary circulation They may be due to air, fat, bacteria, a neoplasm, or a blood clot.

BLOOD DYSCRASIAS AND HEART DISEASE

Disorders affecting individual blood elements may produce structural and physiological changes of the heart and blood vessels. Therefore, specific diseases affecting the red and white blood cells and the platelets will be considered. (See also Chap. 11.)

Diseases of the Red Cells. Several important disorders of the red blood cell may affect the cardiovascular apparatus if severe or prolonged in nature.

SECONDARY ANEMIA. Hypoxia due to anemia produces effects which are similar to those seen in diseases which interfere with respiration, coronary insufficiency, carbon monoxide or cyanide poisoning, or excessive methemoglobin formation. In the presence of advanced and chronic forms of anemia, fatty degenerative changes occur; these may affect myocardial efficiency to variable degrees. Cardiac dilatation and hypertrophy also occur. The role of anemia in the production of *interarterial*

coronary anastomoses is of considerable importance They occur in only 10 per cent of normal hearts from patients with normal hemoglobin levels On the other hand, anastomoses are present in 35 per cent of the hearts of patients with antecedent anemia and with hemoglobin values lower than 70 per cent. An adequate oxygen supply to the tissues is maintained in chronic severe anemia by an increased cardiac output, an increased velocity of blood flow, and a relatively more complete extraction of oxygen from the blood as it passes through the capillaries. A decrease in peripheral resistance is related to the increased blood flow. The blood volume is generally slightly reduced but the plasma volume is normal The deviations from the normal values vary, but they are generally distinct when the hemoglobin values are less than 50 per cent.

Cardiac manifestations include palpitation and dyspnea on exertion, tachycardia, cardiac enlargement, murmurs, and electrocardiographic changes The arterial pressure is frequently lowered while the *venous pressure* is generally within normal limits Precordial pain and congestive failure occur in some patients and disappear as the anemia is alleviated In fact, *precordial pain* may be the predominating complaint in many patients suffering from severe chronic anemia. It persists until the anemia is relieved The problem of differentiating the exertional dyspnea, edema, and hepatomegaly associated with severe anemia, from those associated with heart failure due to coronary disease, frequently presents itself Diagnostic aid is derived from the fact that, in anemia, there is neither venous engorgement nor orthopnea.

In addition to the characteristic hematologic findings, there is an increased cardiac output which occurs as a compensatory mechanism Anemia produces a shortened circulation time and tends to decrease blood viscosity, vascular resistance, and blood pressure. The electrocardiogram reveals a tendency to *low voltage* of the QRS complex, isoelectric or inverted T wave, and S-T depression. These changes disappear if the anemia is corrected The enlargement of all heart chambers also decreases with appropriate measures

SICKLE-CELL ANEMIA. This disease is chronic, hereditary, familial, and almost exclusively confined to Negroes It is frequently associated with myocardial involvement and chronic cardiac failure. Cardiac changes are due to thrombosis of the small vessels of the heart and lungs, as well as to the anoxemic effects of the marked anemia. An asymptomatic sickle-cell trait (*sicklemia*) is found in about 8 per cent of all Negroes A small proportion (6 to 8 per cent) of them develops a marked anemia and characteristic symptoms (sickle-cell anemia). The anemia, systemic thromboses, fever, jaundice, and cardiac findings may be confused with the signs of acute rheumatic fever or bacterial endocarditis.

The abnormal shape of the erythrocytes is responsible for the stasis of blood flow in the capillaries; this results in thrombosis, infarction, necrosis, and hemorrhage. Secondary peripheral vasospasm also aids in this process. Degenerative changes are enhanced by the anemic phase. The heart becomes dilated and hypertrophied with a pale myocardium. The cardiac weight ranges between 225 and 440 Gm. Microscopic changes include interstitial edema, myocardial degeneration, vacuolated sarcoplasm, Zenker's degeneration, and interstitial infiltration by white cells. An extreme tortuousness of the blood vessels develops, and the occlusive involvement of the small pulmonary arteries may result in *chronic cor pulmonale*.

The symptoms include weakness, fatigability, and pallor. The signs are mainly due to vascular occlusions with infarctions of the spleen, brain, heart, and kidneys Therefore, signs referable to any of these organs may be found. Sinus arrhythmia and tachycardia are frequent. There is a diffuse heart enlargement A *diastolic tap* may be felt over the pulmonic area, and a *systolic thrill* is frequently present over the precordium. A systolic murmur of variable intensity may be loud enough to obscure the 1st apical sound, or a presystolic murmur may blend with the 1st sound. These murmurs are frequently mistaken for those due to rheumatic or congenital heart disease. Signs of right-sided failure (*cor pulmonale*) may eventually appear Roentgenograms reveal a globular enlargement of the heart and a prominence of the pulmonary conus. Bone changes are diagnostic. Electrocardiographic changes may occur, due to thrombosis of small coronary vessels If the injury has not been too extensive, reversal of the process may take place.

splashing or churning noises due to the presence of liquid and air. Roentgenograms and aspiration reveal specific changes.

Chylopericardium. True *chylopericardium* does occur, and pseudochylous fluids may be aspirated from the pericardial sac following indirect or direct trauma to the thoracic duct or due to neoplastic or tuberculous invasion of the duct. Aspiration of a milky fluid is characteristic. Pseudochylous fluid does not contain fat, but it has a milky appearance due to the presence of fine albuminous particles.

Acute Nonspecific (Idiopathic) Pericarditis. Acute nonspecific pericarditis pursues a relatively benign clinical course without evidence of any associated or primary disease. (See Part 8, Chap. 3.) Recognition of these cases is highly desirable since their differentiation from other types of pericarditis and myocardial infarction is of great importance. Although the causative factor remains obscure, it is a frequent sequela to upper respiratory infections. The possibility that the disease represents an antigen-antibody reaction with sensitization of the pericardium and subsequent inflammatory reaction on exposure to bacterial antigen cannot be excluded A history of recurrent attacks may be obtained in a fair number of cases. This susceptibility to reinfection is similar to that seen in rheumatic fever. The involved areas of the pericardial sac lose their normal glistening appearance and become dull and opaque. Fibrin deposits may advance to the stage where the heart surface has a shaggy appearance ("bread and butter" type). The fibrinous character of the exudate diminishes as the fibrinous effusion appears in variable amounts. The diagnosis rests upon the history of upper respiratory infection, or unexplained fever and other transitory evidence of mild infection. Severe chest pain, dyspnea, fever, and pericardial friction rub occur Paracentesis reveals fluid with no bacterial content. Roentgenograms and electrocardiograms are highly distinctive. Elevation of RS-T segments and peaked T waves are characteristic.

UNCOMMON DISEASES OF THE CORONARY ARTERIES

A large number of neglected conditions affecting the coronary arteries may occur, some of which are of increasing clinical importance

Most anomalies of the coronary circulat consist of a displacement of the origin of or the other of the main coronary arteries to a slightly abnormal location or absence a primordial vascular bud. There is a quent association with other congenital anor lies, such as transposition of the great vess Thus, a single coronary artery may occur the left coronary artery may originate from pulmonary artery. Subendocardial fibroela sis has been attributed to the resultant ar emia. Anomalies of secondary and tert branches are also possible. For example, left circumflex artery may arise from the r coronary artery. Supernumerary coronary teries and coronary arteriovenous fistulas h also been reported. Congenital necrosis of media of coronary arteries has also been scribed (Gruenwald).

Specific infections and parasitic disea such as syphilis (see Part 9) and malaria Part 8), are considered elsewhere.

Aneurysms of the coronary arteries are ally of congenital or embolic-mycotic ori Arteriosclerosis, syphilis, and collagen dise have also been at fault on occasion.

Emboli may interfere with the coronary culation. They may be due to air, fat, bact a neoplasm, or a blood clot.

BLOOD DYSCRASIAS AND HEART DISEASE

Disorders affecting individual blood ments may produce structural and physio cal changes of the heart and blood ves Therefore, specific diseases affecting the and white blood cells and the platelets be considered. (See also Chap. 11.)

Diseases of the Red Cells. Several impor disorders of the red blood cell may affect cardiovascular apparatus if severe or prolon in nature.

SECONDARY ANEMIA. Hypoxia due to an produces effects which are similar to t seen in diseases which interfere with res tion, coronary insufficiency, carbon mono or cyanide poisoning, or excessive methe globin formation. In the presence of adva and chronic forms of anemia, fatty degen tive changes occur; these may affect myo dial efficiency to variable degrees Car dilatation and hypertrophy also occur. The

and white or gray, but may become hemorrhagic In general, hemorrhage is more common in the acute form and is associated with thrombocytopenia Fatty degeneration may also occur as a result of the accompanying anemia. This is the probable cause of progressive heart failure.

Pericardial involvement frequently gives rise to a hemorrhagic fluid, from which the characteristic cells may be centrifuged and identified after staining Myocardial invasion may affect the conduction system, as well as the myocardium. The resultant clinical and electrocardiographic picture may thus assume many forms

The diagnosis of leukemic infiltration of the heart may be suspected when the hematologic diagnosis has been established and there are cardiac symptoms and signs with progressive electrocardiographic changes. Fluoroscopy and kymography may reveal localized areas of absent pulsations in affected areas.

Diseases of the Platelets. The presence of an increased or decreased number of platelets in the circulating blood may affect the cardiovascular apparatus. The increased production of platelets with an instability of suspension appears to be the pathological process occurring in an unusual disorder known as *essential thrombophilia* This situation favors widespread thrombus formation Thus, the vessels of the extremities, heart, brain, and kidneys may become involved The diagnosis may be established by the elevated platelet count, plasma coagulability studies, and increased plasma globulin fraction in the presence of multiple thrombosis without evidence of underlying vascular damage

A quantitative or qualitative deficiency of the platelets is associated with a tendency to hemorrhage. Purpura is due to a significant reduction in the number of platelets and is known as *thrombocytopenic purpura* Many blood disorders may be associated with this condition and include various anemias and leukemias, as well as numerous infectious and certain splenic disorders The effects on the cardiovascular apparatus are not only those due to bleeding into the myocardium and around blood vessels, but also those due to the secondary effects of the chronic blood loss Diagnostic studies include (1) a platelet count, (2) bleeding time, (3) clot retraction, and (4) a tourniquet test.

METABOLIC DISORDERS AND THEIR EFFECTS ON THE CARDIOVASCULAR SYSTEM

The cardiovascular system may be affected by certain metabolic disorders. In most instances, specific endocrine dysfunctions are involved; in some cases, enzyme systems are at fault. Hormones elaborated by the endocrine system act by augmenting or inhibiting the activity of specific enzyme systems Overactivity or underactivity of the glands may result in cardiopathies that are more or less characteristic Many chemical events require the presence of highly specialized protein catalysts known as *enzyme systems*. The effect of hormones is discussed in Part 2, Chap 29. Disorders of endocrine glands are discussed in Chap 10.

The Thyroid Gland. THYROTOXIC HEART DISEASE. The occurrence of cardiovascular involvement during hyperthyroidism is well recognized. The disease occurs most frequently during the second and third decades of life The incidence in women is much higher, being in the ratio of 5:1. However, since men are more severely affected, a relatively higher percentage of cardiac involvement is found in this group

Excessive secretion of thyroxin results in increased metabolic function which obviously makes greater demands upon the cardiovascular system Increased oxygen consumption is associated with an elevated cardiac output Persistent overactivity results in variable degrees of hypertrophy of the heart muscle. Eventually, the cardiac reserve becomes completely exhausted and congestive heart failure ensues The direct toxic effect of thyroxin on the heart muscle may add to the strain on the myocardium, as well as cause intractable atrial fibrillation It becomes evident much sooner in the presence of other underlying heart disease Myocardial edema, necrosis, and fibrosis, due to direct thyrotoxic effects, have been described but their existence is not accepted by all investigators.

The course of thyrotoxic heart disease is variable depending on the age of the patient and severity and duration of the intoxication

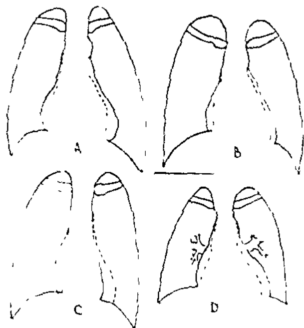

Fig. 16-2. The effects of *specific therapy on the* heart size. A. *Myxedema* showing generalized cardiac enlargement. Dotted lines indicate reduction in size after 2 months of treatment with thyroid extract. B. Thyrotoxicosis with generalized increase in heart size. Dotted lines show decreased size as *metabolic* rate is improved after 4 months of therapy with propylthiouracil C. Addison's disease revealing marked decrease in the cardiac silhouette. *Dotted lines show* increase in size one month following treatment with *adrenocortical extract* and sodium chloride. D Pernicious anemia. Note *generalized* cardiac enlargement and prominence of hilar markings After 2 months of intensive specific therapy, there is *return to normal* (dotted lines).

Depression of the R-T junction and flat or *inverted T waves* are commonly noted

PERNICIOUS ANEMIA Pernicious anemia is a chronic disease which is characterized by an insidious onset, macrocytic hyperchromic anemia, achylia gastrica, and disturbances of the *gastrointestinal, nervous,* and cardiovascular systems.

The heart is dilated and hypertrophied, frequently weighing up to 600 Gm The muscle layers appear pale, with microscopic evidence of diffuse fatty degeneration This produces yellow streaks at the venous end of the capillaries. This has been referred to as *tiger-lily heart.* Evidence of congestive failure is found terminally.

The symptoms referable to the circulatory system may be so pronounced as to lead to a mistaken diagnosis of primary cardiovascular disease. Symptoms include dyspnea, dependent edema, and precordial pain. Weakness, fatigability, palpitation, basal rales, and even ascites, may occur. Signs include a systolic murmur over the apical, pulmonic, or aortic areas, or *a diffuse systolic murmur* over the entire precordium. A *diastolic murmur* occasionally heard over the aortic area is attributed to dilatation of the aortic ring. Hypotension, premature beats, and tachycardia are common. Congestive failure may eventually appear.

The hemogram is diagnostic. Absence of free gastric acid following histamine injection is characteristic. The circulation time may be shortened. The electrocardiogram reveals S-T depression, flattening of T waves, and low voltage of the QRS complex in the severe forms. Roentgenograms reveal diffuse cardiac enlargement during the advanced stage of the disease *(Fig. 16-2D)*.

POLYCYTHEMIA. In both primary and secondary polycythemia, there is an increased viscosity of the blood and an increased blood volume. Cardiovascular involvement is common Although hypertrophy and dilatation are noted, the vascular manifestations are of greater significance since multiple thromboses of the arteries and veins are frequently observed. The coronary vessels may thus become involved, giving rise to a clinical and electrocardiographic picture characteristic of coronary occlusion Cerebral and other vascular thromboses and hemorrhage have also been observed. Hypertensive and arteriosclerotic changes are generally considered to be coincidental The myocardium presents a dark-red appearance.

Diseases of the White Cells: Leukemias. Leukemic infiltrations of the heart commonly occur in about one-third of all cases of lymphatic or myeloid leukemia. It was originally held that all heteroplastic leukemic nodules represent metastatic growths of embolic cells. The engorgement of myocardial capillaries with leukemic cells, frequently observed, seems to support *this view*

Besides affecting the mediastinal structures, which can indirectly affect the heart, leukemic infiltrations may invade the cardiac tissues directly These areas are not sharply demarcated, as are *most primary* and secondary tumors. Less *frequently, they* may have a nodular appearance. They are generally firm

bones (osteitis fibrosa cystica). Increased excretion of calcium phosphate results in the precipitation of renal calculi. Pyelonephritis is a frequent complication and a significant number of patients develop hypertension or renal insufficiency. The arteriovenous effect of cystic disease of the bones and *calcification of the myocardium and arteries* may also develop. The electrocardiogram reveals an abnormally abbreviated electrical systole (*short Q-T*). This finding is not specific since it also occurs with digitalis. However, the S-T segments and T waves are not depressed in hyperparathyroidism

HYPOPARATHYROIDISM Decreased secretion of parathormone may occur as the result of cystic degeneration, atrophy, or inflammation of the parathyroid glands, or of accidental removal at the time of thyroidectomy This results in a reduction in serum calcium and signs of neuromuscular hyperexcitability, such as painful spasms The most characteristic electrocardiographic change is *prolongation of the Q-T interval*. This change may also be found when the serum calcium is lowered in other disease processes, also in heart strain and myocardial ischemia

The Pituitary Gland. ACROMEGALY AND GIGANTISM Cardiac enlargement is found in association with acromegaly but it is not yet definite whether this is a feature characteristic of the generalized splanchnomegaly Heart weights have been found to average 450 Gm and may exceed 1,200 Gm Microscopy shows that the increased bulk is due to hypertrophy of the individual fibers of muscle tissue with marked lacy interstitial fibrosis. Cardiac failure and death occur in about one-fourth of the cases The occurrence of peripheral circulatory disturbances is probably due to dysfunction of the autonomic nervous system Hypertension is frequently observed but is due to concomitant hyperfunction of the basophilic portion of the gland

BASOPHILISM A basophilic adenoma of the pituitary gland is most frequently found in patients with Cushing's syndrome Occasionally, an adenoma of the adrenal cortex or a carcinoma of the thymus is at fault The clinical picture reveals painful adiposity confined to the face (moon face), neck, and trunk Kyphosis, sexual dystrophy, hypertrichosis in females, a dusky plethoric appearance associated with polycythemia, purple abdominal striae, and variable pains and fatigability, are typical findings. Hypertension is a common finding and results in hypertrophy and dilatation of the heart, arteriolar nephrosclerosis, and thickening of the arterioles in all organs of the body.

The Adrenal Glands. HYPERFUNCTION OF THE ADRENAL CORTEX Hyperfunctioning lesions of the adrenal cortex produce a variety of clinical syndromes, but only *Cushing's syndrome* falls within the scope of this text. It may be caused by a basophilic adenoma of the pituitary or by a primary hyperplasia or tumor of the adrenal cortex. An overproduction of the active adrenal compound desoxycorticosterone results in salt and water retention, edema, hypertension, and eventually congestive heart failure. The urinary 17-ketosteroids are markedly elevated, and hypochloremic alkalosis may be encountered.

HYPOFUNCTION OF THE ADRENAL CORTEX: ADDISON'S DISEASE A destructive lesion of the adrenal cortex is characterized by asthenia, pigmentation of skin and mucous membranes, gastrointestinal and nervous disturbances, and *hypotension* Tuberculosis, cysts, primary atrophy, or malignant destruction are the most important pathogenetic factors Hormonal insufficiency is reflected in increased blood levels of cholesterol, nonprotein nitrogen, and potassium, and in decreases in chloride, sodium, glucose, and hydrogen-ion concentration Excessive loss of water through the kidneys results in a negative water balance and a loss of threshold substances in the urine. The subsequent shifts of water and electrolytes from the tissues to the blood accounts for the alterations in the blood constituents. In a significant number of patients, the heart is small both in volume and weight (Fig. 16-3C), and there is an increase in the hemofuscin pigmentation of the myocardium Marked hypotension and myocardial weakness occur The electrocardiogram reveals *low voltage* of QRS complexes and T waves. Analysis of the serum reveals low sodium and chloride, and high potassium levels The ACTH test shows a decrease in circulating eosinophils

HYPERFUNCTION OF THE ADRENAL MEDULLA: PHEOCHROMOCYTOMA. Pheochromocytoma (paraganglioma) is a chromaffin tumor arising either in the adrenal medulla or in chromaffin

Palpitation and dyspnea are the first important symptoms. Vague precordial pain of a paroxysmal nature is common. Forceful pulsations of the precordium and of the large arteries are easily palpated and may be visualized. A *bruit* heard over the inferior poles of the thyroid gland is due to the greatly increased blood supply of this gland. A functional systolic murmur of harsh character may be heard to the left of the sternum. It is usually attributed to the increased pulmonary circulation with dilatation of the pulmonary artery. Wide pulse pressure is due to moderate elevation of the systolic pressure and slight decrease in the diastolic pressure. The systolic pressure rarely exceeds 160 mm Hg. Occasionally, there may be confusion with aortic insufficiency. Cardiac enlargement occurs eventually in most cases (Fig. 16-2B). Common disturbances of rate and rhythm are sinus tachycardia and atrial fibrillation, but extrasystoles, atrial flutter, and supranodal tachycardia are not unusual

Fluoroscopy reveals markedly increased activity of the cardiac contractions The outflow tract of the left ventricle may show the earliest evidence of cardiac hypertrophy and there is prominence of the pulmonary artery. The ECG is not diagnostic. Besides possible arrhythmias, low or inverted T waves may be found, especially in lead II. Left ventricular strain patterns become evident in long-standing cases. Tracer tests with radioactive iodine (I^{131}) are considered diagnostic for hyperthyroidism The protein-bound iodine level and basal metabolic rate determination are not quite as accurate, but are more readily available Circulation times are markedly decreased

MYXEDEMATOUS HEART DISEASE. Cardiac dysfunction due to underactivity of the thyroid gland occurs in approximately three-fourths of untreated cases. The disease occurs at any age and has no sex predominance

The initiating causes of the hypothyroid state are (1) insufficient thyroid activity associated with thyroglandular atrophy, (2) pituitary dysfunction, (3) too radical thyroid extirpation for thyrotoxicosis, (4) overtreatment with antithyroid compounds, or (5) excessive use of radioactive iodine for coronary heart disease or myocardial insufficiency As a result, the heart undergoes enlargement, partly because of the myxedematous state of the cardiac structures and partly because of hydropericardium and cardiac dilatation (Fig 16-2A). The musculature, which appears translucent and light red, may dilate to such an extent that a functional insufficiency of the atrioventricular valves results. Although the microscopic changes are not specific, an edematous material is usually found between the muscle fibers. The frequent association of premature arteriosclerosis, especially of the coronary arteries, is probably due to an increase in blood cholesterol level which is secondary to the thyroid dysfunction

Cardiac symptoms may not become evident unless sudden demands are made upon the decreased cardiac reserve. Dyspnea becomes more pronounced as congestive failure progresses. Precordial pain is due to the frequent association of coronary artery sclerosis However, it may also follow thyroid therapy since the sudden increase in metabolism may result in relative coronary insufficiency. Bradycardia is a constant finding Cardiac enlargement is due to increased bulk as well as to dilatation although hydropericardium may also contribute. Weakness of the heart sounds may be evident, because of sluggish heart action Relative mitral and tricuspid insufficiency may appear as a result of cardiac dilatation.

Roentgenograms show a generalized increase in heart size. Fluoroscopy, roentgen kymography, and electrokymography show markedly decreased pulsations despite the increased heart size. The therapeutic response to specific therapy is striking and diagnostic within a few weeks. Characteristic electrocardiograms show sinus bradycardia, low voltage of the QRS complexes, and flat or inverted T waves in the standard and chest leads. There may be varying degrees of AV block These findings disappear with appropriate therapy Other studies reveal decreased cardiac output and prolonged circulation time. Blood cholesterol levels are high while protein-bound iodine levels are diminished. The glucose tolerance curve is flat. Basal metabolic rate is usually below 30 per cent of normal.

The Parathyroid Glands. HYPERPARATHYROIDISM The parathyroid glands secrete a hormone (parathormone) which mobilizes calcium and maintains a normal serum calcium level Hyperplasia or tumor of these glands produces an increase in hormonal secretion which results in calcium mobilization and decalcification of

heart and other organs may suffer deleterious effects. *Insulin hypoglycemia* is due to excessive administration of insulin. When hypoglycemic levels are reached, there is a release of epinephrine and norepinephrine which drives the blood sugar levels above the original peak of hyperglycemia. Hypoglycemic attacks are not likely to occur during the management of young, markedly advanced, or sick diabetic subjects. Attacks are especially deleterious in diabetic patients with congestive failure, acute coronary thrombosis, or severe angina pectoris *Spontaneous hypoglycemia* may be caused by diseases of the endocrine system, such as hyperinsulinism due to hyperplasia or tumors of the islets of Langerhans, Addison's disease, Simmonds' cachexia, or hypothyroidism. Extensive liver disease, such as marked metastatic involvement, cirrhosis, infectious hepatitis, and poisoning, may also be at fault. Disturbances of the nervous system, malnutrition, diarrhea, and renal glycosuria are rare causes

Although neurologic symptoms predominate during a hypoglycemic attack, the cardiovascular system is also involved Hypoglycemia is accompanied by increased cardiac work and may have serious effects on a previously damaged heart Cardiac arrhythmias, hypertensive encephalopathy and coronary heart disease are known to occur. During attacks, elevation of S-T segments, and various arrhythmias are noted in the electrocardiogram. These changes are reversible with therapy.

Glycogen Storage Disease (von Gierke's Disease). Glycogen storage disease is due to a developmental defect involving the enzyme systems necessary for the transformation of glycogen to dextrose and vice versa Since islet hyperplasia is frequently found, there is a possibility that it is a response to the increased demand for insulin Most children with the disease die during the first year of life Although the liver, kidney, and reticuloendothelial system are the main sites for the pathological storage of glycogen, histochemical methods and chemical analysis reveal that the heart has been affected. The heart is moderately enlarged due to the abnormal glycogen storage. Myocardial fibers appear hypertrophied and vacuolized by tiny glycogen deposits The latter appear as large empty spaces which crowd the nuclei toward the periphery of the cells. These deposits cause up to a five-fold increase in the size of the individual myocardial fibers. Because of the diffuse involvement, the electrocardiographic picture is one of combined heart strain When the heart is predominantly involved, cyanosis and dyspnea or unexpected death is the rule

Laboratory tests reveal hypoglycemia and ketosis in the fasting condition. Absence of hyperglycemic response to epinephrine and an abnormal glucose tolerance curve unaccompanied by glycosuria are also noted, as well as decreased glycogenolysis. Normal diastase activity and hypercholesterolemia are found.

Hemochromatosis. Hemochromatosis (*bronze diabetes*) is characterized by the excessive deposition of hemosiderin and hemofuscin in various organs and in the skin. A disordered metabolism of iron in the cytochrome system provides the most plausible explanation. Most of the cases occur in persons more than 35 years old and men predominate in a ratio of 20:1 The pigment deposits produce fibrotic reactions in the liver (portal cirrhosis) and in the pancreas (bronze diabetes) Hence, death occurs as a result of the complications of portal hypertension or diabetes, or following intercurrent infection The average duration of life following diagnosis is 18 months.

French investigators considered the cardiac features so important as to name the disease "syndrome endocrino-hepato-cardiaque." The possible relationship of heart failure to profound endocrine and biochemical changes, such as adrenocortical insufficiency or hypopituitarism, requires further investigation. Myocardial changes include extensive replacement fibrosis, myocardial atrophy, vacuolization, and fatty degeneration Chemical tests reveal an increase in recoverable iron in the myocardium. When pigment deposits in the myocardium become severe enough to produce cellular degeneration, function is interfered with and heart failure may result. There appears to be no correlation between the appearance of failure and the age of onset or duration of disease, the severity or duration of cirrhosis and diabetes, and the occasional presence of hypopituitarism Neither is there any correlation between pathological changes and the abnormalities of cardiac function The latter are manifested by arrhythmias (supraventricular paroxysmal tachycardia, atrial fibrillation and flutter, heart block, and frequent extrasystoles).

tissue located elsewhere in the body. The characteristic clinical picture develops following the irregular release of significant amounts of epinephrine. Paroxysmal attacks of *hypertension* may last from seconds to hours. Palpitation, precordial distress, tachycardia, headache, anxiety, tremulousness, vomiting, glycosuria, and vasomotor phenomena may occur. The systolic pressure usually exceeds 200 mm Hg. When hypertensive attacks are frequent or sustained, cardiac enlargement is almost always present. Massage over the adrenals, bending, or surgical manipulation of the adrenals, may precipitate an attack. Tests with TEA, dibenamine, and benzodioxane produce sharp falls in blood pressure. Perirenal air insufflation may delineate an adrenal tumor mass. The electrocardiographic findings during an attack may show only an increased heart rate Short periods of supraventricular or ventricular tachycardia, or ventricular extrasystoles, have been observed Alterations in T waves are not striking. A left ventricular strain pattern may appear eventually.

ACUTE ADRENOCORTICAL INSUFFICIENCY: WATERHOUSE-FRIDERICHSEN SYNDROME. A small percentage of cases of acute septicemia (meningococcemia, staphylococcemia or gonococcemia) are complicated by extensive hemorrhage of both adrenal glands Massive adrenal hemorrhage may also occur in the newborn infant Malaise, abdominal pain, petechiae, cyanosis, marked hypotension, and shock develop rapidly.

The Pancreas. THE CARDIOVASCULAR COMPLICATIONS OF DIABETES MELLITUS. Diabetes mellitus is a disturbance in the utilization of carbohydrates which is associated with hypofunction of the islet cells This disorder is most important because of its frequency and its serious complications

The duration and degree of diabetes greatly influence the severity of atheromatous degeneration. Thus, coronary artery disease is the most important single cause of death in diabetics. It actually occurs two to five times more frequently in diabetic than in nondiabetic subjects. Marked *arteriosclerosis of the aorta* with uncoiling and widening is fairly common Abdominal aortic aneurysms are likely to develop Fundus changes are eventually discernible in almost every case and consist mainly of microaneurysms. There is a high incidence of arteriosclerosis obliterans in patients with diabetes mellitus. Almost one-third of diabetics of 10 years' (or longer) standing show absent pulsations in one or more extremities. A high rate of hypertension occurs among diabetic patients especially when diabetes is long-standing Congestive failure due to hypertensive and arteriosclerotic heart disease is fairly frequent Earlier diagnosis, new types of insulin (including oral preparations), and the recognition and treatment of extrapancreatic factors in the disease may eventually alter the predominating pathological findings. It is not unreasonable to predict that the premature degenerative changes may become considerably modified in the near future.

Electrocardiographic changes are due to the effects of coronary sclerosis Reversible changes in the electrocardiogram in diabetic acidosis consist of S-T depression, lengthening of the Q-T interval, and inversion of the T waves. The factors which affect the heart are complex and include the disturbed relationship between extracellular and intracellular electrolytes, impaired cardiac nutrition, and the effects of hypoxia and azotemia.

It has long been recognized that, in the late phases of diabetic acidosis, the patient's blood pressure may fall to low levels This change is often irreversible and leads to death within a few hours, it is due to decreased total peripheral resistance, which is below 50 per cent of the normal value The site of this vasodilatation has not been determined The cool, pale skin suggests that cutaneous blood flow is diminished. Electrolyte imbalance, especially of potassium, appears to play an important role.

Renal lesions occurring in diabetes are also important because of their effects on the cardiovascular system Three types of nephropathies are recognizable in diabetes pyelonephritis, arteriolar nephrosclerosis, and intercapillary glomerulosclerosis. Approximately one-third of all diabetic cases with hypertension are associated with intercapillary glomerulosclerosis. This entity is characterized by hyaline deposits between the capillary loops but without associated inflammation or thickened capillary basement membrane

THE EFFECTS OF HYPOGLYCEMIA ON THE HEART (HYPERINSULINISM). When the circulatory glucose is reduced to subnormal levels, the

for the maintenance of a state of good health (see also Chap. 11). These include the proper amount and distribution of organic (proteins, carbohydrates, and fats) and inorganic (minerals) nutrients, as well as the accessory food factors (vitamins).

Endogenous factors concerned with proper nutrition are the adequate digestion and absorption of foodstuffs, hormonal balance, and possible disease of many organs. For example, pancreatic disease may interfere with carbohydrate metabolism, myxedema may allow an excessive accumulation and deposition of fat calories, or sprue may interfere with the metabolism of several nutritive substances.

Exogenous factors include an overabundant or deficient supply of these substances Thus, the spectrum of nutritional disorders which may affect the cardiovascular system ranges from a marked excess to a severe deficiency of any nutrient. In some instances, a single substance may be involved, such as a high level of fat intake However, in most instances, a combination of disturbances occurs. Thus, the influence of starvation may lead to multiple deficiency states. These disturbances will be discussed under two general headings. undernutrition (starvation) and overnutrition (obesity)

Undernutrition. Undernutrition is a problem which constantly affects large segments of the world's population It may assume huge proportions during famines, economic depressions, or wars At other times, it depends upon the uncertainties of climate, nomadic peregrinations, and difficulties in food preservation and transportation Individual factors include the presence of many disease states and the efficiency with which essential materials are utilized Extremes in temperature are also significant since a cold environment increases caloric requirements. Heavy labor demands a greater caloric intake An empty pocket will lead to an empty stomach in any climate. The effects upon the cardiovascular system are few but of enormous consequence. The significance of drastic food restriction over a prolonged interval cannot be overemphasized. The following effects on the heart and blood vessels will be discussed. atrophy of the heart, effects on the blood pressure and cardiac function, nutritional edema, and vitamin and mineral (electrolyte) deficiencies

ATROPHY OF THE HEART. Atrophy of the heart is an integral part of undernutrition and starvation. It may be also associated with neoplasms, chronic infections, and degenerative, metabolic, or endocrine diseases Important factors in the production of emaciation are prolonged illness, bedfastness, fever, surgical procedures, radiation, and gastrointestinal dysfunction. Extreme emaciation is characteristic of anorexia nervosa, Simmonds' cachexia, and Addison's disease.

Pathologic studies recognize two types of atrophy of the heart with about equal incidence *Simple atrophy* is devoid of cellular pigmentation and occurs in younger individuals (average 42 years). The average heart

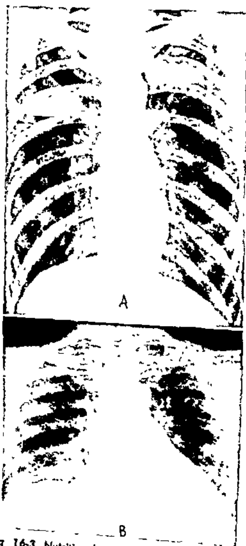

Fig 16-3. Nutritional effects on the heart A. Starvation. B. Obesity.

Right-sided failure is more common than left-sided failure, due to the larger iron content usually found in the right ventricular myocardium. Since these patients exhibit a narrow margin of balance between glycosuria and hypoglycemia, hypoglycemic shock may precipitate failure in a greatly damaged heart.

Primary Xanthomatosis. Primary xanthomatosis is a hereditary disease of the reticular cells due to an intracellular disorder of cholesterol metabolism. Most cases occur in persons under 30 years of age. The serum cholesterol of all relatively young patients with coronary atherosclerosis should be determined as the initial step in uncovering hypercholesterolemia in members of the immediate family. Two types of xanthomatosis are found: that with elevated blood cholesterol level and that with normal level. The former is associated with cardiovascular damage and is considered to be the only familial type of heart disease Although the hereditary nature of this condition has been emphasized by many authors, the mode of transmission is under discussion. Genetic analysis supports the concept that the disturbance of cholesterol metabolism is inherited as an incomplete dominant trait.

The *hypercholesterolemic type* is characterized by cardiovascular involvement, xanthoma of the tendons and tendon sheaths, skin, and bile ducts, with secondary jaundice and biliary cirrhosis, and reticuloendothelial system involvement. The circumscribed, soft, yellow-pink, subcutaneous tumors and the marked elevation of the blood lipids should direct attention to possible cardiovascular involvement, since it has been found that 40 per cent of these patients present coronary artery or peripheral vascular disease. Cardiac symptoms usually develop before the age of 50 *Substernal pain* is a frequent symptom, and electrocardiographic studies reveal progressive changes associated with coronary insufficiency or occlusion. Xanthomatous infiltration may affect the aorta and the cardiac valves causing the production of murmurs Microscopically, large deposits of fatty material are found in the myocardium, in the intima of the coronary and large arteries, and in the valves

Porphyria. Porphyria is a constitutional disturbance of the porphyrin metabolism. The congenital (light-sensitive) form is quite rare but the intermittent acute form is more common. Symptoms usually appear during the second or third decade. The fundamental physiological derangement in acute porphyria is probably due to the occurrence of generalized angiospasm. The vascular changes which occur in acute porphyria have been fairly well established. Hypertension and renal changes, probably due to arteriospasm, occur frequently Nervous manifestations are also common. The red urine which attracts attention to the disease is caused by the presence of uroporphyrin

Ochronosis. Ochronosis is a disturbance of the intermediary metabolism, it is characterized by gray or black pigmentation of all cartilaginous structures, ligaments, and fibrous tissue. Alkaptonuria or melanuria may be found The urine may reveal homogentisic acid, and skin biopsy shows melanin pigment. In the chronic form of the disease, there is a tendency for premature systemic arteriosclerosis to develop.

Gout. The gouty diathesis is a hereditary, constitutional disease associated with a disturbance in purine metabolism, and is frequently characterized by recurrent attacks of acute arthritis due to deposits of sodium urate It is almost entirely limited to men and may occur at any age but is most common during the fourth decade. Hyperuricemia and diminished renal excretion of uric acid are the outstanding laboratory findings Urate deposits may be found in many structures, such as the ears, bursae, and tendons. Their presence has also been reported in the aorta, myocardium, and aortic valves. A foreign-body inflammatory reaction results, which varies in extent and degree with the vascularity of the affected tissues It is well known that the incidence of arteriosclerosis and hypertension is high in gouty subjects Hypertrophy of the left ventricle may result from generalized arteriosclerosis, nephrosclerotic changes, and arterial hypertension Advanced coronary or cerebral vascular disease is frequently the immediate cause of death. Marked arteriosclerotic degeneration of the aorta, terminal pericarditis, and venous thrombosis have also been reported.

NUTRITIONAL DISORDERS OF THE HEART AND BLOOD VESSELS

The body has an optimal daily requirement for the various nutritional factors necessary

lieved to provide insufficient protein for the regeneration of serum proteins, resulting in decrease in the plasma colloid osmotic pressure. Since transudation is a dynamic process, the reduction in serum protein concentration may not be appreciable even with clinical edema. Total serum protein and albumin concentrations of 5 and 2.5 Gm/100 ml respectively, are considered to be the critical levels below which frank edema may be expected to disappear. It is possible that organic changes in the capillary walls provide an additional factor. Nutritional edema must be differentiated from that of congestive heart failure and that of beriberi heart disease.

VITAMIN DEFICIENCIES. Accessory food substances are necessary for the proper metabolism of individual cells and for the catalysis of vital cellular processes. Small amounts obtainable from exogenous *sources are essential*. Specific vitamin deficiencies may occur singly or in combinations during various malnutrition states. Latent or clinically manifest deficiency diseases may affect the normal or diseased cardiovascular apparatus. Unsubstantiated claims and misinformation have been propagated in this particular field. Various vitamin deficiencies as they relate to the heart and vessels will be considered below.

Thiamine Chloride Deficiency (Beriberi Heart Disease). It has become increasingly clear that the manifestations of *beriberi are* subject to great variations. At least three *syndromes* are recognized. *Dry beriberi* is revealed by peripheral neuritis and other nervous system changes while *wet beriberi* presents edema and serous effusions. We are primarily concerned with "beriberi heart *disease*." The disease develops gradually after the patient's subsistence on a grossly deficient *diet for at* least 3 months.

Pathologic changes, e.g., hydropic degeneration *of the* myocardial and conducting fibers, swollen collagen, and interstitial edema with separation of the myocardial bundles, occur *but* are neither specific nor consistently present. *Myocardial fibrosis has* usually been ascribed to diminution of the myocardial blood supply which leads *to scattered* areas of degeneration and replacement fibrosis. Endocardial fibrosis has also been a *frequent* finding. The right-sided chambers of the heart are usually dilated. The heart weight may reach well over 600 Gm. Mural thrombi are frequently found.

Clinically, two types of beriberi heart disease are described. The *acute fulminating form* appears suddenly and results in death when untreated. The more common type is more *chronic* in character and results in congestive heart failure. The following features are necessary to establish a diagnosis of beriberi heart disease: (1) enlarged heart with sinus rhythm; (2) dependent edema; (3) elevated venous pressure; (4) nonspecific electrocardiographic changes, (5) history of 3 or more months of a diet deficient in thiamine; (6) signs of neuritis or pellagra, (7) absence of other causes of heart disease; (8) therapeutic test with clinical recovery and return of heart size and electrocardiogram to normal, or (9) *autopsy* findings consistent with beriberi heart. Cardiovascular manifestations include *dyspnea*, palpitation, tachycardia, and edema. The heart is *often enlarged*, primarily by edema of its wall. However, small hearts are more often seen in the United States. The right or, less commonly, the left ventricle may fail. In occasional *cases, positive* findings are predominantly found in the peripheral circulation and consist of bounding pulse, rapid circulation, overdistended veins in the neck and legs, pistol-shot sounds over the arteries, and sudden circulatory collapse. Thyrotoxic heart disease, nonspecific myocarditis, and neurocirculatory asthenia must be differentiated.

Laboratory studies supply important corroborative evidence. Electrocardiographic changes include bradycardia, *low voltage* of all waves with inversion of T waves, and prolongation of the Q-T interval. The ad*ministra*tion of thiamine chloride results in a *prompt* return to normal and, hence, aids in the *differentiation* from hypothyroidism, which produces a somewhat similar tracing. *Roentgenograms* show a diffuse enlargement of the heart. The right side is usually larger than *the left* and the pulmonary *conus* may be prominent. These changes are also reversible with specific therapy. *Rapid* arm-to-tongue circulation time in the presence of increased venous pressure helps to differentiate *this* from other types of heart failure. Determination of the thiamine concentration of *the blood* or urine, and cal-

weight is 200 Gm. The ratio between heart weight and body weight is 0.48 per cent (normal 0.43 to 0.40 per cent). *Brown atrophy* reveals characteristic bipolar pigment deposits in the muscle cells and occurs in older individuals (average age 62 years). The average heart weight is 230 Gm. The ratio between heart and body weight is normal. In either case the microscopic examination reveals a reduction in size of the muscle fibers Subsequently, evidences of degeneration appear, such as cloudy swelling and loss of striations.

Clinical findings occur as follows:

1. There are reductions in the heart rate, systolic blood pressure, peripheral circulation, and venous pressure.

2. The atrophic heart appears small (Fig 16-3A) or normal in size, with comparatively weak heart tones.

3 A faint precordial or apical *systolic murmur* of functional nature is present in one-fourth of all cases.

4. There is a strikingly low incidence of symptoms and signs of heart failure. Electrocardiographic findings are more or less constant, revealing a progressive diminution of voltage of all complexes and *prolongation of the Q-T interval.*

5. Blood pressure falls in 75 per cent of normotensive cases, and cardiac function is decreased.

Far-reaching observations of large segments of the European population subjected to chronically deficient nutritional states afforded much valuable information. Animal and human experimental studies have also proved enlightening Reports by both Brozek et al and Keys are especially significant

Normal young men were kept on a restricted protein and total caloric intake but without sodium limitation for six months The average body weight fell 24 per cent, the mean systolic blood pressure fell 11 per cent, the mean diastolic pressure fell about 8 per cent, the mean pulse rate decreased to 37, and the average basal metabolic rate decreased to minus 40 per cent Functional studies revealed that the heart decreased in all dimensions and assumed a more upright position in the chest The total volume reduction averaged 16 per cent and the stroke volume reduction averaged 18 per cent. The venous pressure was not more than 50 per cent of the normal level The margin of safety represented by the ratio of metabolism to the oxygen circulating in the blood fell to one-half the normal average. In the first 3 months of rehabilitation on controlled diets, the heart size returned to its original level but other characteristics of cardiac function showed a relatively slower recovery. The heart appeared to be closer to failure during early rehabilitation than during starvation since the stroke volume of the heart was decreased compared with both control and semistarvation values. Vitamin or protein supplements had no significant effect on the recovery rate of cardiovascular function. After 5 months, the work done by the heart was still about 10 per cent below the control, and only one-half of the lost margin of safety was restored
